where PA_{mean} is the mean pulmonary artery pressure and LA is the left atrial pressure. The units of resistance by this formulation (using pressures in millimeters of mercury and pulmonary flow in liters per minute) are Woods units (which can be expressed in dynes/s per cm^5 by multiplying by 80). In the pediatric population, vascular resistance is frequently calculated using the cardiac output indexed to the body surface area (in square meters) with the resulting indexed resistance units of Woods units/ m^2 . PVR may be fixed or reactive, and, at the time of cardiac catheterization, response to nitric oxide or 100% fraction of inspired oxygen (FiO_2) may be assessed.

The management of a patient with a VSD depends on the size of the defect, the type of defect, the shunt volume, and the PVR. In general, patients with large defects who have intractable CHF or failure to thrive should undergo early surgical repair. If the congestive symptoms can be moderated by medical therapy, then surgery may be deferred until 6 months of age. Patients with moderate VSDs may be safely followed. If closure has not occurred by school age, then surgical closure is indicated. Small VSDs with a Q_p/Q_s ratio of less than 1.5 do not require closure unless there is evidence of left-sided chamber enlargement. There is a small long-term risk of endocarditis for these patients, but this can be minimized with the appropriate use of prophylactic antibiotics.²¹ Patients with outlet VSDs have a risk of developing aortic insufficiency due to leaflet prolapse, and, therefore, all of these patients should undergo surgical closure.²² Older children and adults must undergo catheterization to assess the pulmonary circulation. When there is a fixed PVR greater than 8 to 10 Woods units/ m^2 , then surgery is contraindicated.

Surgical closure is performed through a median sternotomy. Cardiopulmonary bypass is employed with bicaval cannulation, and the patient is typically cooled to 32°C. After aortic cross-clamping, cold cardioplegia is delivered through the aortic root to arrest the heart. Exposure of the ventricular septum is most often achieved by making a right atriotomy and retracting the leaflets of the tricuspid valve. This provides access to perimembranous, inlet, and most trabecular VSDs. Outlet VSDs are frequently best exposed via a pulmonary arteriotomy because the defect lies just beneath the valve. Trabecular VSDs located near the ventricular apex can be very difficult to expose, and an apical ventriculotomy may be necessary. Once the defect is exposed, it is closed using a polytetrafluoroethylene patch and a running polypropylene suture, although other centers may prefer other patch material or interrupted suture technique. It is important to understand the anatomy of the conduction tissue when closing VSDs. The AV node is an atrial structure that lies at the apex of an anatomic triangle (known as the triangle of Koch) formed by the coronary sinus, the tendon of Todaro (a prominent band leading from the inferior vena cava and inserting in the atrial septum), and the septal attachment of the tricuspid valve. The node then gives rise to the bundle of His, which penetrates the AV junction beneath the membranous septum. The bundle of His then bifurcates into right and left bundle branches, which pass along either side of the muscular ventricular septum. In the presence of a perimembranous VSD, the bundle of His passes along the posterior and inferior rim of the defect, generally on the left ventricular side. In this critical area, sutures must be placed superficially on the right ventricular side a few millimeters from the edge of the defect. The bundle of His also tends to run along the posterior and inferior margin of inlet VSDs. The conduction tissue is usually remote from outlet and trabecular VSDs.

PA banding is a palliative maneuver that is used to protect the pulmonary circulation from excessive blood flow. PA banding is currently performed only in patients who are felt to be poor candidates for VSD closure, either due to associated illness or due to anatomic complexity, such as multiple trabecular VSDs (“Swiss cheese” septum). Banding is performed without the need for cardiopulmonary bypass. A band is placed around the main PA and tightened to achieve a distal PA pressure of about one-half systemic. The band is secured to the adventitia of the PA to prevent its migration. Distal migration may result in narrowing and poor growth of one or both branch pulmonary arteries, whereas proximal migration can cause deformity of the pulmonary valve. Later, when the patient is a candidate for VSD closure, the band must be removed. Repair of the main PA at the band site is also usually necessary and can typically be accomplished by scar resection and primary closure or patch repair.

Surgical closure of a VSD is associated with a mortality of about 1%.²³ Potential complications include injury to the conduction tissue and injury to the tricuspid or aortic valves. Transient heart block may result from tissue swelling or injury from retraction, but permanent heart block occurs in less than 1% of cases. When heart block develops after surgery, patients are usually observed for a period of 7 to 10 days prior to permanent pacemaker implantation. Closure of perimembranous and inlet VSDs may result in distortion of the tricuspid valve, which may cause significant regurgitation. Aortic valve injury may occur as a result of inaccurate suturing, especially in perimembranous and outlet defects. A residual VSD is seen in about 5% of cases, and reoperation is indicated when significant shunting persists (Q_p/Q_s ratio >1.5). The Q_p/Q_s ratio can be calculated by measuring oxygen saturations and using the following formula derived from the Fick equation:

$$Q_p/Q_s = (A_o - SVC)/(PV - PA)$$

where A_o is the aortic (or systemic) saturation, SVC is the saturation in the superior vena cava, PV is the saturation in the pulmonary veins (which is usually estimated to be 95% to 100%), and PA is the saturation in the pulmonary arteries. Intraoperative echocardiography is used routinely to identify residual defects, which can then be repaired before the patient leaves the operating room.

Recently, transcatheter devices have been developed to allow closure of some VSDs in the cardiac catheterization laboratory or by periventricular deployment without the use of cardiopulmonary bypass.^{24,25} Device closure is optimal for large muscular defects with sufficient rims for securing the device. These defects are often difficult to visualize and close surgically. Periventricular closure allows the use of VSD device closure in smaller infants with symptomatic muscular VSDs with excellent results without the challenges of transvenous access in this population.²⁵ The use of devices for perimembranous VSDs remains limited by the risk of damage to the conduction system or impingement on the function of the tricuspid or aortic valves. A recent series demonstrated a 22% rate of complete heart block, which is prohibitively high in comparison to the surgical rate of complete heart block of less than 1%.²⁶

ATRIOVENTRICULAR SEPTAL DEFECT

Defects in the embryologic development of the endocardial cushions may result in a variety of morphologic abnormalities in the AV valves and the atrial and ventricular septa. These anomalies range from ostium primum ASD to complete AVSD (or AV canal defect), with a spectrum of intermediate forms. PDA and TOF are occasionally seen in association with these defects. A high percentage of patients with abnormalities of

TABLE 81.1

RASTELLI CLASSIFICATION OF ATRIOSEPTAL VENTRICULAR DEFECTS

■ TYPE	■ DESCRIPTION

B	The anterior bridging leaflet is attached to a papillary muscle in the right ventricle.
C	The anterior bridging leaflet is free-floating, with no attachments except to the valve annulus.

the AV structures have trisomy 21 (Down syndrome). All infants with trisomy 21 should have an echocardiogram to rule out congenital heart disease given a prevalence of 50%.

Complete AVSD is an anomaly characterized by a common AV orifice, rather than separate mitral and tricuspid orifices, and a deficiency of endocardial cushion tissue, which results in a primum ASD and an inlet type of VSD. Complete AVSDs were subclassified by Rastelli et al.²⁷ into three types according to the morphology of the anterior leaflet of the common AV valve (Table 81.1). Incomplete AVSDs are variants in which there is partial fusion of the AV valves, resulting in separate right and left AV valve orifices. The ostium primum ASD is a type of incomplete AVSD in which the VSD component is absent.

When both left and right AV valves equally share the common AV valve orifice, the AVSD is termed *balanced*. Occasionally, the orifice may favor the right AV valve (right dominance) or the left AV valve (left dominance). In marked right dominance, the left AV valve and LV are hypoplastic, and frequently coexist with other left-sided abnormalities, including aortic stenosis, hypoplasia of the aorta, and coarctation. Conversely, marked left dominance results in a deficient right AV valve with associated hypoplasia of the right ventricle, pulmonary stenosis or atresia, and TOF. Patients with severe imbalance require staged single-ventricle reconstruction.

The conduction tissue is displaced in an AVSD and is at risk during surgical repair. The AV node is located posteriorly and inferiorly of its normal position toward the coronary sinus in what has been termed the *nodal triangle*. This triangle is bounded by the coronary sinus, the posterior attachment of the inferior bridging leaflet, and the rim of the ASD. The bundle of His courses anteriorly and superiorly to run along the leftward aspect of the crest of the VSD, giving off the left bundle branch and continuing as the right bundle branch.

A number of other cardiac anomalies are associated with AVSDs including a PDA (10%) and TOF (10%).²⁸ Important abnormalities of the left AV valve include single papillary muscle (parachute mitral valve) (2% to 6%) and double orifice mitral valve (8% to 14%).²⁹ A persistent left superior vena cava with or without an unroofed coronary sinus is encountered in 3% of patients with an AVSD. DORV (2%) significantly complicates or may even preclude complete surgical correction.²⁸ Left ventricular outflow tract obstruction from subaortic stenosis or redundant AV valve tissue occurs in 4% to 7%.^{30,31}

Patients with an incomplete AVSD generally present in a similar fashion as a patient with a large secundum ASD. Patients with a complete AVSD with both atrial and ventricular level shunting generally present early in infancy with signs and symptoms of CHF. In addition, moderate or severe left AV valve regurgitation occurs in approximately 10% of patients with an AVSD, worsening the clinical picture. On physical examination, the precordium is hyperactive, often with a prominent thrill. Auscultatory findings include a systolic murmur along the left sternal border, a high-pitched murmur at the

apex from left AV valve regurgitation, and a middiastolic flow murmur across the common AV valve. In the presence of elevated PVR, there may be a split first heart sound. Significant cardiomegaly and pulmonary overcirculation are found on the chest radiograph. Electrocardiography (ECG) reveals biventricular hypertrophy, atrial enlargement, prolonged PR interval, leftward axis, and counterclockwise frontal plane loop. Doppler/echocardiography is diagnostic, defining the atrial and ventricular level shunting, valvular anatomy, and any associated anomalies. Cardiac catheterization should be performed for patients older than 1 year of age, for patients with signs or symptoms of increased PVR, or in some cases to further evaluate other associated major cardiac anomalies. If the PVR is high, it is important to remeasure it while the child is breathing 100% oxygen with and without nitric oxide. If the pulmonary resistance falls, it implies that much of the elevated resistance is dynamic and can be managed in the perioperative period by ventilatory manipulation, supplemental oxygen, and nitric oxide. More recently, sildenafil has been shown to decrease elevation in PVR in children with CHF.³² Markedly elevated pulmonary resistance (>10 Woods units/ m^2) that does not respond to oxygen administration is generally considered a contraindication to repair.

Operative treatment is almost always necessary as soon as symptoms are observed to prevent further clinical deterioration. Even in the absence of symptoms, operation is best performed before 6 months of age. PA banding, which permits delaying the repair until the child is larger, is no longer used today except in select complex or single-ventricle cases, extremely low birth weight or prematurity, and very poor clinical condition. This approach exposes the child to the risks of two operations, and the overall mortality exceeds that of primary repair in infancy.

Correcting AVSDs requires patch closure of both septal defects, with any necessary valve reconstruction. Separate atrial and ventricular patches or a single patch for both chambers can be used.³³ During closure of the ventricular defect, the surgeon must carefully avoid injury to the conduction system, which passes along the posterior and inferior rim of the ventricular septum.

The short- and long-term success of the operation is highly dependent on the status of the PVR and the surgeon's ability to maintain competence of the mitral valve. Although earlier reports recommend that the cleft in the left AV valve should not be closed and the valve treated as a trileaflet structure, most surgeons now believe that closure of the cleft is an important mechanism in preventing postoperative left AV valve regurgitation. Significant AV valve regurgitation at the conclusion of surgery, severe dysplasia of the left AV valve, and failure to close the cleft of the left AV valve have been identified as important risk factors for reoperation.³⁴ Significant postoperative left AV valve regurgitation is also a risk factor for operative and long-term mortality.^{30,34} The cleft should not be completely closed in the presence of a single papillary muscle to avoid causing left AV valve stenosis. In the case of a double-orifice valve, the bridging tissue should not be divided to create a single opening in the valve.

Operative mortality is related largely to associated cardiac anomalies and left AV valve regurgitation. Mortality for repair of uncomplicated incomplete AVSDs ranges from 0% to 0.6%, and the addition of left AV valve regurgitation increases mortality to 4% to 6%.^{30,35} For complete AVSDs, the mortality without left AV valve regurgitation is approximately 5%, compared with 13% when significant degrees of regurgitation are present.³⁰

The majority of reoperations after repair of AVSD are due to left AV valve regurgitation or subaortic stenosis with reoperation rates at 5 years of 11% and 10%, respectively.³⁶ Significant postoperative AV valve regurgitation occurs in 10% to 15% of patients, necessitating reoperation for valve repair or replacement in 7% to 12%.^{34,37,38} Long-term survival

is excellent with rates at 1, 3, and 5 years of 98%, 95%, and 95%, respectively.³⁶

TETRALOGY OF FALLOT

- 5** TOF is the most common cyanotic congenital heart defect. It occurs in 0.6 per 1,000 live births and has a prevalence of about 5% among all patients with congenital heart disease.⁷ The pathologic anatomy is frequently described as having four components: VSD, overriding aorta, PS, and right ventricular hypertrophy (Fig. 81.3). Embryologically, the anatomy of TOF is thought to result from a single defect: anterior malalignment of the infundibular septum.³⁹ The infundibular septum normally separates the primitive outflow tracts and fuses with the ventricular septum. Anterior malalignment of the infundibular septum creates a VSD due to failure of fusion with the ventricular septum and also displaces the aorta over the VSD and right ventricle. Infundibular malalignment also crowds the right ventricular outflow tract, causing PS and, secondarily, right ventricular hypertrophy. Prominent muscle bands also extend from the septal insertion of the infundibular septum to the right ventricular free wall and contribute to the obstruction of the right ventricular outflow tract. The pulmonary valve is usually stenotic and is bicuspid in 58% of cases.⁴⁰ Pulmonary atresia occurs in about 7% of cases of TOF. The branch pulmonary arteries in TOF may exhibit mild diffuse hypoplasia or discrete stenosis (most frequently of the left PA at the site of ductal insertion). Coronary artery anomalies are frequently present. The origin of the left anterior descending from the right coronary artery, which occurs in 5% of cases, is clinically important because the vessel crosses the right ventricular infundibulum and is vulnerable to injury at the time of surgery. A right aortic arch is present in 25% of patients with TOF. Associated defects include ASD, complete AVSD, PDA, or multiple VSDs.

Patients with TOF develop cyanosis due to right-to-left shunting across the VSD. The degree of cyanosis depends on the severity of obstruction of the right ventricular outflow tract. Frequently, cyanosis is mild at birth and may remain undetected for weeks or months. Neonates with severe infundibular obstruction or pulmonary atresia will develop symptoms shortly after birth and will require a prostaglandin infusion to maintain ductal patency to ensure adequate PBF. In other patients, the right ventricular outflow tract obstruction

FIGURE 81.3. The four anatomic features of tetralogy of Fallot. The primary morphologic abnormality, anterior and superior displacement of the infundibular septum, results in a malalignment ventricular septal defect, overriding of the aortic valve, and obstruction of the right ventricular outflow. Right ventricular hypertrophy is a secondary occurrence.

is minor, and the predominant physiology is that of a large VSD with left-to-right shunting and CHF.

The occurrence of intermittent cyanotic spells is a well-known feature of TOF. The etiology of spelling is still controversial but is clearly related to a transient imbalance between pulmonary and systemic blood flow. A spell may be triggered by hypovolemia or peripheral vasodilation (e.g., after a bath or vigorous physical exertion). Spells may occur in neonates, but are most frequently reported in infants between the ages of 3 and 18 months. Most spells resolve spontaneously within a few minutes, but some spells may be fatal. Older children have been observed to spontaneously squat to terminate spells. The squatting position is thought to increase systemic vascular resistance, which thereby favors PBF.

Cyanosis is the most frequent physical finding in tetralogy. Auscultation reveals a normal first heart sound and a single second heart sound. A systolic ejection murmur is present at the left upper sternal border. Older children may develop clubbing of the fingers and toes. Chest radiography typically demonstrates a boot-shaped heart due to elevation of the cardiac apex from right ventricular hypertrophy. Pulmonary vascular markings are usually reduced. A right aortic arch may be present. An ECG shows right ventricular hypertrophy. Echocardiography is definitive, and catheterization is not necessary in most cases.

The medical management of TOF is directed toward the treatment and prevention of cyanotic spells. The immediate treatment of the spelling patient includes administration of oxygen, narcotics for sedation, and correction of acidosis. Transfusion is indicated for anemic infants. α -Agonists are useful for increasing systemic vascular resistance (which favors PBF). Some centers have used beta-blockers as a form of long-term therapy to suppress the incidence of spells.

All patients with TOF should undergo surgical repair. Asymptomatic patients should be repaired electively between 4 and 6 months of age. Early repair is indicated for neonates with severe cyanosis and for infants who have had a documented spell or worsening cyanosis.

Classically, the repair of TOF was accomplished in two stages. During the first stage, PBF was augmented by creating a connection (or shunt) between a systemic artery and the PA. At the second stage, the shunt was taken down, and a complete repair was performed. The first shunt procedure was the Blalock-Taussig shunt, in which the subclavian artery was mobilized and divided distally, and an end-to-side anastomosis was created between the inferiorly deflected subclavian and the ipsilateral PA. Other shunt operations were subsequently developed and involved connections between the ascending aorta and right PA (Waterston shunt) or between the descending aorta and left PA (Potts shunt). The modified Blalock-Taussig shunt is the most common type of shunt used today and consists of an interposition graft (polytetrafluoroethylene) between the innominate or subclavian artery and the ipsilateral PA. Creation of a shunt may be accomplished with or without the use of cardiopulmonary bypass.

Currently, one-stage repair of TOF is preferred by most centers. Initial palliation with a shunt is still indicated for some patients who are at high risk for early complete repair, such as those with multiple congenital anomalies, severe concurrent illness, intracranial hemorrhage, or an anomalous coronary artery crossing a hypoplastic infundibulum. In the absence of these risk factors, complete repair in the symptomatic neonate can be performed with lower mortality and reoperation rate compared to staged palliation.^{41,42}

Complete repair of TOF is performed using a median sternotomy and cardiopulmonary bypass with bicaval venous cannulation. By a transatrial approach, the right ventricular outflow tract can be examined through the tricuspid valve. Muscle bundles obstructing the right ventricular outflow tract are divided or rarely resected. The VSD is closed with a patch. Pulmonary valvotomy is performed, when indicated, via a ver-

tical incision in the main PA. When the pulmonary valve annulus or infundibulum is severely hypoplastic, a transannular outflow tract patch may be necessary to relieve the obstruction. When an anomalous coronary artery crosses the infundibulum, a transannular incision may be contraindicated. In these cases, and in patients with pulmonary atresia, placement of a conduit (cryopreserved homograft, valved xenograft, or bioprosthetic heterograft) between the right ventricle (via a separate ventriculotomy) and main PA will be necessary. Patients who have a transannular patch develop pulmonary insufficiency as a consequence. This is surprisingly well tolerated in most infants and children, as long as the tricuspid valve is competent. As these patients grow older, some will develop right ventricular failure due to chronic pulmonary insufficiency, and pulmonary valve implantation may be necessary, often in the second or third decade of life.^{43,44}

The early mortality following repair of TOF is between 1% and 5%.^{40,45} The results are worse for patients with TOF and pulmonary atresia. Long-term complications include recurrent obstruction of the right ventricular outflow tract and development of right ventricular dysfunction due to chronic pulmonary insufficiency. Actuarial survival at 20 years is 86% with excellent functional status.⁴⁶

DOUBLE-OUTLET RIGHT VENTRICLE

Double-outlet ventricle includes a variety of malformations in which, by 50% or more, both great arteries arise from one ventricle. Although double-outlet LVs occur, a far more common anomaly is the double-outlet right ventricle (DORV). A VSD is usually present in DORV, in addition to other defects, including discordant ventriculoarterial connections, valvar or subvalvar stenosis of the PA and aortic outflow, and single ventricle.

The physiologic consequences of DORV vary depending on the associated defects. The three most critical factors determining the net effects on the circulation are the size of the VSD, the presence or absence of PS, and the presence and degree of left-sided obstruction. As a result, DORV may clinically resemble an isolated VSD, TOF, or transposition of the great arteries.

The size and location of the VSD are important considerations in planning operative management. The VSD may be primarily directed toward the aorta, toward the PA, equally toward both arteries (doubly committed), or remote from both great vessels (noncommitted). The location of the VSD affects the direction of flow of oxygenated blood and thus affects the degree of cyanosis. VSDs in DORV seldom close spontaneously. This is fortunate, as closure would result in severe hemodynamic decompensation or death.

If the VSD is large, nonrestrictive, and committed to the aorta, it can be closed with a tunnel-like patch that directs left ventricular flow into the aorta. A restrictive VSD must be enlarged to avoid creating subaortic stenosis. For patients with DORV and PS, repair requires right ventricular outflow tract reconstruction with a patch or a valved allograft conduit, in addition to patch closure of the VSD.

DORV with transposition-type physiology (malposed great vessels with the VSD committed to the PA), also known as a Taussig-Bing anomaly, may be treated by a variety of methods, depending on the specific anatomic details. The preferred approach would be to perform an arterial switch operation, thus making the VSD committed to the aorta, and baffling the left ventricular outflow from the VSD to this neo-aorta. Another preferred approach, which depends on a favorable orientation of the two great vessels and VSD, would be an intraventricular tunnel from the VSD to the aorta. A third approach utilizes the Damus-Kaye-Stanzel operation (DKS).

During the DKS, the proximal PA is anastomosed end to side into the aorta. The VSD is baffled to both semilunar valves, which both connect to the aorta. An extracardiac conduit is then placed to reconstruct right ventricle-to-PA continuity. This approach may also be useful when the VSD is doubly committed or noncommitted, so that making a direct connection to either single great vessel is problematic.

The current results for correction of DORV with subaortic VSD are excellent, with a 15-year survival, including hospital mortality, of 96%.^{47,48} Mortality for the more complex repairs tends to be slightly higher. Hospital mortality for an arterial switch operation with VSD closure for DORV ranges from 3.7% to 14.3%.^{49,50}

TRANSPOSITION OF THE GREAT ARTERIES

6 Transposition of the great arteries (TGA) is a congenital cardiac anomaly in which the aorta arises from the right ventricle and the PA originates from the LV (ventriculoarterial discordance; Fig. 81.4). Looping refers to the right or left looping of the primitive heart tube during fetal development, which determines whether the atria and ventricles are concordant (right atrium attaches to right ventricle and left atrium attaches to LV) or discordant. Levo-TGA (l-TGA) is associated with AV discordance (right atrium attaches to LV and left atrium attaches to right ventricle), and is also termed *congenitally corrected TGA*. l-TGA is a rare variant of TGA and is beyond the scope of this chapter, which will focus on dextro-TGA (d-TGA). The defect can be subdivided into d-TGA with intact ventricular septum (IVS) (55% to 60%) and d-TGA with VSD (40% to 45%), one third of which are hemodynamically insignificant. Pulmonic stenosis (PS), causing significant left ventricular outflow tract obstruction, occurs rarely with an IVS and in approximately 10% of d-TGA/VSD.⁵¹

d-TGA is a relatively common cardiac anomaly and is the most common form of congenital heart disease presenting as cyanosis in the first week of life. The malformation accounts for approximately 10% of all congenital cardiovascular malformations in infants.⁵² The degree of cyanosis depends on the amount of mixing between the pulmonary and systemic circulations. In d-TGA, oxygenated pulmonary venous blood is returned to the lungs and desaturated systemic blood is returned to the body. Because the two circulations exist in parallel, some mixing between them must occur to allow

oxygenated blood to reach the systemic circulation and the desaturated blood to reach the lungs. Mixing may occur at a number of levels, most commonly at the atrial level through an ASD or a PFO. Generally, two levels of mixing are necessary to maintain adequate systemic oxygen delivery with a VSD or PDA serving as an additional site for cardiac mixing. In d-TGA, there can be no fixed shunt in one direction without an equal amount of blood passing in the other direction; otherwise, one circulation would eventually empty into the other. Therefore, the amount of desaturated blood reaching the lungs (effective PBF) must equal the amount of saturated blood reaching the aorta (effective systemic blood flow). Clinical characteristics are dependent on the degree of mixing and the amount of PBF. These factors relate to the specific anatomic subtype of d-TGA. Neonates with d-TGA with IVS (or small VSD) have mixing limited to the atrial level and PDA. The ASD may be restrictive and the PDA generally will close over the first days to week of life. As the degree of mixing decreases, the patient becomes increasingly cyanotic and will eventually suffer cardiovascular collapse. Fortunately, the majority of these neonates will manifest cyanosis early in life, which is recognized by a nurse or physician within the first hour in 56% and in the first day in 92%.⁵³ In d-TGA with a large VSD, there is additional opportunity for mixing and increased PBF. The neonate with d-TGA/VSD may only manifest mild cyanosis, which may be initially overlooked. However, generally within 2 to 6 weeks signs and symptoms of CHF will emerge. Tachypnea and tachycardia become prominent, whereas cyanosis may remain mild. Auscultatory findings are consistent with CHF with increased PBF, including a pansystolic murmur, third heart sound, middiastolic rumble, gallop, and narrowly split second heart sound with increased pulmonary component. Neonates with d-TGA and significant PS present with severe cyanosis at birth. Lesser degrees of PS will result in varying levels of cyanosis. The ECG is normal at birth, demonstrating the typical pattern of right ventricular dominance. Although the classic chest radiographic appearance of an egg-shaped heart with a narrow superior mediastinum may be seen, this finding is often obscured by an enlarged thymic shadow. The abnormal ventriculoarterial connection is clearly seen on echocardiography, which demonstrates that the posterior great vessel arising from the LV is a PA that bifurcates soon after its origin. The anterior great vessel is the aorta and arises from the right ventricle. Associated lesions, including VSD, left ventricular outflow tract obstruction, and coarctation, may also be diagnosed. Although used less frequently, cardiac catheterization may be helpful to confirm the basic anatomy, discern associated lesions, define the coronary anatomy, and improve cardiac mixing by means of balloon atrial septostomy.

The infant with d-TGA and severe cyanosis requires prompt diagnosis and treatment to improve mixing and increase the arterial oxygen saturation. The first intervention to improve mixing in a cyanotic newborn suspected of having d-TGA is to ensure ductal patency by beginning an infusion of prostaglandin E₁ (PGE₁). In the presence of a restrictive ASD, a balloon atrial septostomy, a technique developed by William Rashkind⁵⁴ in 1966, is performed. The procedure involves inserting a balloon-tipped catheter across the foramen ovale into the left atrium. Inflation and forcible withdrawal of the catheter tears the septum primum and enlarges the ASD. Mixing generally increases immediately, with a substantial increase in arterial oxygen saturation.

Without intervention, d-TGA is universally fatal. Untreated, 30% of neonates will die in the first week of life, 50% by the first month, 70% within 6 months, and 90% by 1 year.⁵⁵ The definitive surgical treatment of patients with d-TGA has changed dramatically in the past decade with the advent of the arterial switch operation. Before this procedure, repair of d-TGA was generally delayed until patients were at least 6 months of age. Historically, palliative procedures were often

FIGURE 81.4. Anatomy of the most common type of transposition of the great arteries. The location of the ascending aorta is usually anterior to and to the right of the pulmonary artery.

FIGURE 81.5. The Mustard operation for transposition of the great arteries. In this procedure, the atrial septum is excised and replaced with a pericardial baffle, so that pulmonary venous blood is redirected over the baffle to the tricuspid valve. Superior and inferior vena caval blood then drains to the mitral valve.

necessary to improve the systemic saturation or protect the pulmonary vascular bed before definitive repair. If balloon atrial septostomy failed to enlarge the ASD adequately, a Blalock-Hanlon septectomy was performed. Rarely used today, this operation is a method of surgically enlarging the ASD without cardiopulmonary bypass. In patients with large VSDs, significant CHF and pulmonary hypertension are present early in life. Historically, the main PA was banded to reduce distal PA pressure and prevent the development of pulmonary vascular occlusive disease. Changes of pulmonary vascular disease may develop in about 25% of patients with hemodynamically large VSDs by 3 months of age; therefore, early reduction of PA pressure was essential. In those cases of transposition with severe left ventricular outflow tract obstruction, total pulmonary flow is reduced and systemic-to-PA shunting was undertaken until definitive repair could be accomplished.

Historically, definitive repair was achieved by redirecting venous inflow at the atrial level. First successfully performed by Senning⁵⁶ in 1959, the operation was further modified by Mustard⁵⁷ in 1964 (Fig. 81.5). In both techniques, the atrial septum is repositioned such that superior and inferior vena caval blood is rerouted to the mitral valve and then to the LV and PA. Pulmonary venous blood is redirected to the tricuspid valve and right ventricle. The right ventricle then ejects the oxygenated blood to the systemic circulation. The Mustard operation uses a large patch of pericardium or prosthetic material to create the intra-atrial baffle. In the Senning procedure, the patient's atrial tissue is used, and little or no foreign material is necessary. Although physiologic repair at the atrial level is associated with a low operative mortality rate (<5%), even in infants, a number of late problems have occurred. Obstruction to vena caval inflow, particularly at the junction of the superior vena cava and the right atrium, still occurs in about 5% of patients and may be more common when the procedure is performed in an infant. Additionally, pulmonary venous obstruction may develop and is often difficult to repair. Perhaps because of the complex atrial suture lines, atrial dysrhythmias are common and occur in more than half of patients observed on a long-term basis. In addition, pacemakers may be necessary for troubling bradyarrhythmias in as many as 10% of these patients.

The most serious long-term complication of repair by either the Senning or Mustard technique has been right ventricular dysfunction. Right ventricular failure with an enlarged, poorly contractile chamber and secondary tricuspid regurgitation has

been found in a significant number of these patients in long-term follow-up studies. The true incidence of significant right ventricular failure in these cases remains difficult to define and is clearly influenced by an earlier era of operation with different methods of myocardial protection and surgical technique. The fact that many of these infants underwent definitive repair after many months of significant cyanosis may also have influenced right ventricular function.

The long-term complications of atrial repair prompted a reexamination of direct arterial repair for transposing the great arteries. The "arterial switch" operation, first successfully performed by Jatene in 1975, has become the optimal surgical procedure for infants with this condition.⁵⁸ Current techniques have reduced the operative mortality to levels comparable with those of atrial repair. Additionally, because the operation is performed early in life, this approach has virtually eliminated the interim morbidity and mortality associated with postponement of surgery until at least 6 months of age. The operative technique involves transection of both great vessels and direct reanastomosis to reestablish ventriculoarterial concordance (Fig. 81.6). Additionally, the coronary arteries are removed from the anterior aorta and relocated to the posterior great vessel (neoaorta). The extensive experience gained with this procedure has confirmed that any variant of coronary artery anatomy can be successfully repaired. Certain coronary anatomy variants were previously felt to be associated with higher risk; however, this concern has been neutralized in recent series.^{59,60} Many patients with d-TGA have an IVS, and left ventricular pressure falls early in life as PVR decreases. In this situation, it is essential that the arterial repair be performed within the first 1 to 2 weeks of life, while the LV is still able to meet systemic workloads. In patients presenting later, the LV can be retrained with a preliminary PA banding and an aorticopulmonary shunt, if necessary, followed by the definitive arterial repair. Although patients with large VSDs do not require early repair because they maintain systemic left ventricular pressures, experience has indicated that, even in this subgroup, the operation is best performed within the first month of life, before secondary complications such as pulmonary hypertension, CHF, or infection develop.

Patients with fixed left ventricular outflow tract obstruction are not candidates for the arterial repair because correction would result in systemic ventricular outflow tract obstruction. Most of these patients also have large VSDs. Palliation early in life with systemic-to-PA shunting is an option, with definitive repair postponed until somatic growth results in cyanosis as

FIGURE 81.7. The Rastelli procedure for transposition of the great arteries with ventricular septal defect and pulmonary stenosis. A prosthetic patch placed within the right ventricle directs left ventricular blood through the defect to the aorta. The main pulmonary artery is ligated, and right ventricular blood then passes through a conduit to the distal pulmonary arteries.

the shunt is outgrown. At that time, the Rastelli procedure is performed, in which left ventricular blood is redirected through the VSD and to the anterior aorta by placement of an intraventricular patch (Fig. 81.7). The PA is ligated, and right ventricle-to-distal PA continuity is reestablished with a valved conduit. An increasing number of experienced centers currently recommend early complete repair in the neonatal period using a Rastelli procedure. Early repair eliminates the interim morbidity and mortality associated with a systemic-to-PA shunt and chronic cyanosis.

Current hospital survival for the arterial switch operation ranges from approximately 90% to 98%.^{51,59–62} In earlier eras, d-TGA/IVS had a lower operative mortality than d-TGA/VSD; however, recent studies have neutralized this difference.^{59,60} Complex d-TGA including d-TGA/VSD/PS and d-TGA/VSD with aortic arch hypoplasia are independent predictors of increased operative mortality.^{63,64} Coronary artery anatomy does not affect mortality.⁵⁹ Long-term survival at 5 to 10 years and 15 years ranges from 87% to 93% and 86% to 88%, respectively.^{60–62} The most common cause for reintervention is supralvalvular pulmonic stenosis, occurring in 3.9% to 16%.^{61,62} Late follow-up of arterial switch operation patients has led to increased concern regarding coronary artery patency and neo-aortic root dilation.⁶⁵

TRUNCUS ARTERIOSUS

Truncus arteriosus is a rare anomaly that accounts for 0.4% to 4% of all cases of congenital heart disease.^{66–68} A single arterial vessel arises from the heart, overriding the ventricular septum and giving rise to the systemic, coronary, and pulmonary circulations. Two classification schemes have been proposed: one by Collett and Edwards⁶⁹ in 1949 and the other by Van Praagh and Van Praagh⁷⁰ in 1965 (Fig. 81.8). The Collett and Edwards classification focused on the origin of the pulmonary arteries from the common arterial trunk (Table 81.2). The system offered by Van Praagh and Van Praagh, a somewhat more surgically oriented scheme, is based on the presence or absence of a VSD, the degree of formation of the aorticopulmonary septum, and the status of the aortic arch (Table 81.3).

Persistent truncus arteriosus is the result of failed development of the aorticopulmonary septum and subpulmonary infundibulum (conal septum). Normal septation leads to the development of both pulmonary and systemic outflow tracts, division of the semilunar valves, and formation of the aorta and pulmonary arteries. Failure of septation results in a VSD (absence of the infundibular septum), a single semilunar valve, and a single arterial trunk. Most cases are associated with a

TABLE 81.2**COLLETT AND EDWARDS CLASSIFICATION OF TRUNCUS ARTERIOSUS**

■ TYPE	■ DESCRIPTION
I	Common arterial trunk gives rise to a main pulmonary artery and the aorta.
II	Right and left pulmonary arteries arise directly and in close proximity from the posterior wall of the truncus.
III	Right and left pulmonary arteries arise from more widely separated orifices on the posterior truncal wall.
IV	Branch pulmonary arteries are absent. Pulmonary blood flow is derived from aorticopulmonary collaterals.

VSD reminiscent of the VSD associated with TOF. However, in this anomaly, the superior margin of the defect is formed by the truncal valve. The truncal valve leaflets are generally dysmorphic, and their motion may be restricted. Leaflet number is highly variable, with about 65% tricuspid, 22% quadricuspid, 9% bicuspid, and rarely unicuspid or pentacuspid.⁷¹ As a result of these abnormally developed valve leaflets, a moderate or greater degree of truncal insufficiency is present in 20% to 26% of patients.^{72,73} Mild stenosis is common; however, significant stenosis is present in only 4% to 7%.^{72,73} Significant obstruction is predicted by gradients of more than 30 mm Hg in the presence of a normal cardiac output.⁷⁴ The PAs are usually of normal size and most often arise from the left posterolateral aspect of the truncal artery, often in close proximity to the truncal valve and ostium of the left coronary artery.

Other cardiac anomalies are common, with a PFO usually present. A true ASD is found in 9% to 20%, a persistent left superior vena cava in 4% to 9%, and mild tricuspid valve stenosis in 6%.^{28,75} An interrupted aortic arch, most commonly type B, is present in association with truncus arteriosus (Van Praagh type A4/B4) in approximately 10% to 20%.^{76,77} The arch is rightward, generally with mirror-image branching, in 21% to 36%.^{75,77} Aberrant origins of the brachiocephalic vessels are

reported, most commonly an aberrant right subclavian artery in 4% to 10%.^{75,78} Coronary ostial abnormalities are of particular surgical significance and occur in 37% to 49% of cases.⁷⁹ The left coronary artery is frequently noted to have a high origin, not uncommonly near the takeoff of the pulmonary arteries. Rarely, the left coronary can originate from the main pulmonary trunk or a branch PA.⁷⁸ Extracardiac anomalies are reported in approximately 28% of patients with truncus arteriosus.⁷² Described abnormalities include skeletal, genitourinary, and gastrointestinal deformities. As mentioned earlier, monoallelic microdeletion of chromosome 22q11 is common, with DiGeorge syndrome diagnosed in at least 11%.⁷²

The anatomy of truncus arteriosus results in the obligatory mixing of systemic and pulmonary venous blood at the level of the VSD and truncal valve, which produces arterial saturations of 85% to 90%. The systemic arterial saturation depends on the volume of pulmonary blood flow, which in turn is determined by the PVR. As the PVR begins to fall, excessive pulmonary circulation ensues and leads to pulmonary congestion and signs and symptoms of CHF. This nonrestrictive left-to-right shunt may cause early development of irreversible pulmonary vascular obstructive disease.

The presence of truncal valve abnormalities poses further hemodynamic burdens. Truncal valve regurgitation leads to ventricular dilatation and low diastolic coronary perfusion pressures that can result in myocardial ischemia. Truncal valve stenosis promotes ventricular hypertrophy, increases the myocardial oxygen demand, and limits coronary and systemic perfusion, especially with the large volume of runoff into the pulmonary vascular bed.

Neonates with truncus arteriosus present with signs of CHF and collapsing peripheral pulses. Chest radiography shows marked cardiomegaly; pulmonary plethora, often with minimal thymus shadow; and a right aortic arch. The ECG most often depicts biventricular hypertrophy. Echocardiography is the diagnostic procedure of choice and can demonstrate the truncal vessel, the structure and function of the truncal valve, associated lesions such as interrupted aortic arch, and often the pulmonary arterial anatomy. Cardiac catheterization is not performed unless the anatomy is unclear, further information is needed about the status of the truncal valve, or the status of the pulmonary vasculature is unclear (i.e., infants older than 3 months at diagnosis).

The natural history of patients born with truncus arteriosus is early demise. Approximately 40% of infants are dead within 1 month, 70% by 3 months, and 90% by 1 year.⁸⁰ Early death is caused by CHF. Survivors may do well for a period of time until the development of pulmonary vascular obstructive disease and Eisenmenger syndrome. The ultimate treatment of truncus arteriosus is surgical correction in the neonatal period. Medical treatment is palliative and directed toward controlling CHF with fluid restriction, diuretics, digitalis, and afterload reduction. Complete repair entails separating the pulmonary arteries from the truncus, repairing the resulting defect in the aorta, closing the VSD, and restoring the continuity of the right ventricular outflow tract with an extracardiac conduit. Severe truncal valve regurgitation requires truncal valve repair⁸¹ or replacement, which is best done with a cryopreserved allograft. An associated interrupted aortic arch is repaired by constructing a primary end-to-end anastomosis of the distal ascending aorta with proximal augmentation if necessary.

The results of truncus arteriosus repair have improved greatly during the last two decades. Before the importance of early operation to avoid irreversible PVR was appreciated, patients underwent repair at most institutions at an average age of 2 to 5 years with high mortality rates. Ebert et al. showed that repair in the first 6 months of life is not only possible, but also preferable, reporting a mortality rate of 9%.⁸² Current hospital mortality for the neonatal repair of truncus arteriosus ranges between 4.3% and 17%, with the majority of deaths occurring in complex truncus arteriosus or in truncus

TABLE 81.3**VAN PRAAGH AND VAN PRAAGH CLASSIFICATION OF TRUNCUS ARTERIOSUS**

■ TYPE	■ DESCRIPTION
A	With a VSD
B	Without a VSD
1	The aorticopulmonary septum is partially developed (partially separate main pulmonary artery).
2	The aorticopulmonary septum is absent (no main pulmonary artery segment); both branch pulmonary arteries arise from the common trunk.
3	Either branch pulmonary artery is absent.
4	Hypoplasia, coarctation, atresia, or absence of the aortic isthmus is associated with a large PDA.

PDA, patent ductus arteriosus; VSD, ventricular septal defect.

arteriosus with associated severe truncal valve regurgitation.^{72–74,83–85} Risk factors for poor outcome identified in various studies include significant truncal regurgitation, need for truncal valve replacement, birth weight less than 2.5 kg, presence of interrupted aortic arch or coronary artery anomalies, pulmonary reconstruction with a technique other than valved heterograft or allograft, and age older than 100 days.^{72–74,83–87} Other recent studies have demonstrated that interrupted aortic arch has been neutralized as a risk factor.^{74,84}

AORTIC STENOSIS

Aortic stenosis (AS) refers to a form of left ventricular outflow tract obstruction that may occur at the valvar (70%), subvalvar (25%), or supra-valvar (5%) level (Fig. 81.9). Aortic stenosis occurs in about 4% of patients with congenital heart disease.⁷ The severity of AS may be graded by echocardiography or catheterization. Classification by echocardiography peak instantaneous pressure gradient is mild (<40 mm Hg), moderate (40 to 70 mm Hg), and severe (>70 mm Hg). Classification by catheterization peak-to-peak pressure gradient is mild (<30 mm Hg), moderate (30 to 50 mm Hg), and severe (>50 mm Hg).

Valvar AS occurs secondary to maldevelopment of the aortic valve. Most commonly, a bicuspid valve is present, although tricuspid and unicuspid valves are also represented. In valvar AS, the leaflets are thickened and frequently dysmorphic, and there is a variable degree of leaflet fusion along the commissures. The aortic annulus may be hypoplastic. In 20% of cases, valvar AS is associated with other cardiac defects, most commonly coarctation of the aorta, PDA, VSD, or mitral stenosis. Males with valvar AS outnumber females by a ratio

of 4:1. There is a wide spectrum of clinical presentation of valvar AS, but patients tend to present in one of two groups: younger patients (neonates and infants) with severe AS develop symptoms of rapidly progressive CHF, whereas older patients, with less severe obstruction at birth, have a more indolent course.

Severe AS is usually well tolerated during fetal development. Although left ventricular output and antegrade flow across the aortic valve are decreased, the right ventricle compensates with increased output, and systemic perfusion is maintained by flow across the ductus. After birth, there is increased venous return to the left heart, and this exacerbates the pressure load created by the stenotic aortic valve, leading to left ventricular dysfunction. As the ductus closes during postnatal life, systemic malperfusion may develop with resulting hypotension, acidosis, and oliguria. Coronary perfusion is also impaired due to the combination of systemic hypotension and elevated left ventricular end-diastolic pressure. Patients with critical AS typically exhibit severe left ventricular dysfunction. These patients show signs of distress soon after birth. On examination, there is impaired distal perfusion with poor capillary refill and diminished, thready pulses. A systolic ejection murmur may be absent if the cardiac output is severely diminished. Differential cyanosis may be observed due to perfusion of the lower body with desaturated blood shunting through the ductus. The ECG shows left ventricular hypertrophy, and the chest radiograph displays cardiomegaly and pulmonary congestion. Echocardiography establishes the diagnosis.

Fetal echocardiography has allowed for early diagnosis of critical aortic stenosis. For some, this may predict the progression to hypoplastic left heart syndrome or may result in irreversible left ventricular dysfunction. A few centers in the United States have been able to successfully balloon dilate the aortic valve in utero to promote left ventricular growth and preserve function in select cases.^{88–90}

The neonate or infant with critical AS represents a true emergency. Endotracheal intubation and inotropic support are routine. Ductal patency is maintained with prostaglandins, and acidosis is corrected. All patients with critical AS require some form of urgent intervention. The approach is determined by the valve morphology and by the presence of associated defects. In its most extreme form, critical AS may be associated with underdeveloped left-sided cardiac chambers and therefore may represent a form of hypoplastic left heart syndrome. In these cases, single-ventricle palliation must be undertaken. For patients with adequate left-sided chambers, relief of AS may be achieved by one of the following three approaches: percutaneous balloon valvuloplasty, surgical valvotomy, or aortic valve replacement. Balloon valvuloplasty is generally considered the procedure of choice when the aortic valve annulus is adequate and there are no associated cardiac defects. Alternatively, surgical valvotomy may be accomplished by closed or open techniques. The closed approach is performed using cardiopulmonary bypass, but without aortic cross-clamping. Dilators of increasing size are passed through a ventriculotomy in the left ventricular apex and advanced across the aortic valve. Some centers prefer open surgical valvotomy, which allows a precise valvotomy under direct vision, although aortic cross-clamping with cardioplegia is necessary and results are similar to transventricular dilation. In all cases, the goal of therapy is to relieve stenosis without creating excessive aortic insufficiency. Dramatic clinical improvement is expected following balloon or surgical valvotomy, and early survivals of greater than 80% have been reported regardless of approach.^{91,92} The incidence of aortic insufficiency is slightly higher following balloon valvotomy. In most cases, however, stenosis will recur and repeat valvotomy or aortic valve replacement will eventually be required. Aortic valve replacement is problematic in the neonate due to small patient size. In these cases, many consider the best valve replacement to be a pulmonary autograft

FIGURE 81.9. Anatomy of the types of congenital aortic stenosis. A: Valvar aortic stenosis. B: Supra-valvar aortic stenosis and its repair (*inset*). C: Diffuse (tunnel) subvalvar aortic stenosis. D: Discrete subvalvar aortic stenosis.

(Ross procedure)⁹³ with enlargement of the aortic annulus (Konno aortoventriculoplasty).⁹⁴ The Ross-Konno procedure has been used successfully for neonates with critical AS in whom the aortic annulus is hypoplastic and for selected patients in whom valvuloplasty was unsuccessful. Survival following the Ross-Konno procedure in infants has been shown to be excellent.⁹⁵ Growth of the pulmonary autograft has been documented, thereby making it an ideal valve replacement for children. Unfortunately, as part of the Ross procedure, the pulmonary valve must be replaced using a cryopreserved homograft that does not grow, and homograft replacement must be anticipated at intervals as the patient grows.

In contrast to infants with critical AS, older children with valvar AS usually present with less severe stenosis (mild or moderate), and most are asymptomatic. Symptoms of angina, syncope, and CHF are not commonly reported. Congenital valvar AS is a progressive lesion, however, and survival is dependent on the severity of stenosis and the rate of its progression. Sudden cardiac death is the most common cause of mortality. Endocarditis occurs in less than 1% of patients. The diagnosis of valvar AS in older children can frequently be made on physical exam. There is a classic systolic crescendo-decrescendo murmur at the upper sternal border, which radiates to the neck. An ejection click is often present. A visible apical impulse is suggestive of significant left ventricular hypertrophy. In severe cases, the pulse may be weak and delayed (pulsus tardus et parvus). The ECG shows left ventricular hypertrophy. The chest radiograph is usually normal. Echocardiography accurately defines the level of stenosis and its severity. Using Doppler techniques, the pressure gradient across the stenotic valve may be estimated using a simplified form of Bernoulli's equation, $P = 4V^2$, where P is the pressure gradient and V is the peak flow velocity. Cardiac catheterization is generally reserved for therapeutic intervention.

All patients with severe valvar AS should undergo intervention, as should all symptomatic patients with moderate stenosis. Asymptomatic patients with mild or moderate stenosis are generally observed. As described previously for critical AS, the techniques used to relieve AS in older patients include percutaneous balloon valvuloplasty, surgical valvulotomy, and valve replacement. Balloon valvuloplasty is usually performed as the primary intervention, and is associated with a success rate of nearly 90% and a mortality of less than 1%.⁹⁶ Open surgical valvotomy is an alternative approach with similar results.⁹⁷ For valves that are severely dysplastic, develop restenosis after intervention, or become insufficient as a result of prior intervention, valve replacement may be necessary. For older children, there are more options for valve replacement. The choices include mechanical prostheses, bioprosthetic valves, and tissue substitutes, such as porcine xenografts, cryopreserved human allografts, and pulmonary autografts (Ross procedure). The mechanical valves are the most durable, but require chronic anticoagulation. The bioprosthetic and tissue valves do not require long-term anticoagulation, but tend to deteriorate over time (with the exception of the pulmonary autograft). The pulmonary autograft has the potential advantage of growth but the homograft used to replace the pulmonary valve will require replacement. Selection of the appropriate replacement valve is a complex decision that requires input from all involved parties.

Subvalvar AS occurs below the level of the aortic valve and may be discrete (80%) or diffuse (20%). Discrete (or membranous) subaortic stenosis is rarely seen in infants and tends to progress over time. This lesion consists of a crescentic or circumferential fibrous or fibromuscular membrane that protrudes into the left ventricular outflow tract. The pathogenesis of discrete subaortic stenosis is unknown, but it is thought to be an acquired lesion that develops secondary to a congenital abnormality of the left ventricular outflow tract in which abnormal flow patterns lead to endocardial injury with resul-

tant fibrosis. Although the aortic valve leaflets are usually normal in discrete subaortic stenosis, the turbulent flow created by the obstruction can cause leaflet thickening and progressive aortic insufficiency. Diffuse subaortic stenosis is a more severe form that creates a long, tunnel-like obstruction. Diffuse subaortic stenosis should be distinguished from hypertrophic cardiomyopathy. Both forms of subaortic stenosis are associated with a high risk of endocarditis. The clinical findings in subvalvar AS are similar to those for valvar stenosis.

Intervention for discrete subvalvar stenosis is usually undertaken when the gradient exceeds 30 to 50 mm Hg or when aortic insufficiency is present. In these patients, resection of the membrane is readily performed by a transaortic approach. To reduce the incidence of restenosis, we advocate concurrent performance of a septal myomectomy to alter the geometry of the left ventricular outflow tract.⁹⁸ Operative mortality approaches zero. The recurrence rate of discrete stenosis following membrane resection and myomectomy has been reported to be as low as 4%.⁹⁹ Complications associated with membrane resection can include heart block, VSD, or damage to the aortic or mitral valve leaflets.

The indications for operative intervention in diffuse subaortic stenosis are similar to those for valvar stenosis. When diffuse subaortic stenosis is associated with hypoplasia of the aortic annulus, repair is best achieved with a Konno aortoventriculoplasty, whereby an incision is carried across the aortic annulus and subjacent ventricular septum, the opening patched, and an aortic valve implanted. Patients with an adequate aortic annulus may undergo a septoplasty (modified Konno), in which the septal incision is confined to the immediate subvalvar area and a patch is used to widen the left ventricular outflow tract without replacing the aortic valve. Despite the technical complexity of repair for diffuse subaortic stenosis, excellent results have been reported with high survival and freedom from reoperation.¹⁰⁰

Supravalvar AS is characterized by thickening of the wall of the ascending aorta. The lesion may be localized (80%) to the region of the sinotubular ridge (at the level of the valve commissures), creating an hourglass deformity, or it may be more diffuse (20%), extending into the aortic arch and its branches. In both varieties, the aortic valve leaflets may be abnormal. The free edges of the aortic valve leaflets may adhere to the aortic wall in the region of intraluminal thickening, and this may lead to reduced coronary blood flow during diastole. Aortic wall thickening may also extend into the coronary ostia and further impair coronary blood flow. Associated cardiac lesions are common, particularly branch PA stenoses. A genetic basis for supravalvar AS has been established.¹⁰¹ About 50% of cases of supravalvar AS are associated with Williams syndrome, in which a partial deletion of chromosome 7 (including the elastin gene) leads to the triad of supravalvar stenosis, mental retardation, and a characteristic "elfin" facies. Isolated mutations in the elastin gene have also been shown to produce familial supravalvar AS with an autosomal dominant pattern of transmission. There is a significant incidence of endocarditis in patients with supravalvar AS. Sudden death is frequently reported and is probably related to coronary obstruction.

The signs and symptoms of supravalvar AS are similar to those in other forms of left ventricular outflow tract obstruction. The diagnosis is made by echocardiography, but cardiac catheterization (and more recently magnetic resonance imaging [MRI]) is essential to define the aortic, coronary, and pulmonary arterial anatomy prior to surgical intervention.

Operative intervention is indicated for patients with supravalvar AS in whom the gradient exceeds 50 mm Hg. A number of operations have been proposed for the treatment of localized supravalvar stenosis. The classic repair involves a longitudinal incision across the obstruction in the ascending aorta, which is extended into the noncoronary sinus. The thickened, hypertrophic ridge is resected by endarterectomy

and the aortotomy is augmented with an elliptical patch. A variation of this repair involves creation of an inverted-Y aortotomy with one limb of the Y extended into the noncoronary sinus and the other into the right coronary sinus. A Y-shaped patch is then used to augment the aortotomy. Finally, the Brom repair is performed by transection of the ascending aorta beyond the supravalar ridge. Separate incisions are then made through the supravalar ridge into each sinus of Valsalva. Triangular patches are placed to augment each of these incisions, thereby relieving the supravalar obstruction. Reconnection of the aortic root to the ascending aorta completes the repair. The repair of the diffuse type of supravalar stenosis is performed under circulatory arrest with extensive patching of the ascending aorta, transverse arch, and involved arch arteries. Branch pulmonary stenoses are best managed using transcatheter techniques.

The results of surgery for localized supravalar AS are generally good with low operative mortality and excellent long-term survival.^{102–104} The diffuse form is more difficult to treat, and recurrence is more likely. Overall results are much worse when severe bilateral PA stenoses are present.

COARCTATION OF THE AORTA

Coarctation of the aorta is a narrowing of the proximal descending thoracic aorta distal to the origin of the left subclavian artery, near the insertion of the ductus arteriosus (or ligamentum arteriosum). The severity of luminal narrowing and the length of the aorta affected are variable. Coarctation is thought to occur as a result of ectopic tissue from the ductus arteriosus, which migrates into the wall of the adjacent aorta. After birth, as the ductus closes, the ectopic tissue in the aorta also constricts. Frequently, a posterior shelf of tissue is present at the point of most severe obstruction. The aortic obstruction caused by coarctation creates a pressure load on the LV.

The incidence of coarctation is about 0.5 per 1,000 live births, and its prevalence is 5% of congenital heart defects.⁷ Coarctation is commonly associated with other heart defects including bicuspid aortic valve (in more than 50% of cases), PDA, and VSD. Other left-sided obstructive lesions may also be present, such as aortic arch hypoplasia, AS, mitral stenosis, and left ventricular hypoplasia. Coarctation is also recognized to occur in association with Turner syndrome.

Patients with severe coarctation present in the newborn period. Aortic obstruction is so significant that perfusion of the lower body is dependent on flow from the ductus arteriosus. Spontaneous ductal closure typically worsens the aortic obstruction and may lead to malperfusion of tissues distal to the coarctation. The pressure load on the LV may precipitate CHF. Patients may develop shock with severe acidosis, oliguria, and diminished distal pulses. Infants with severe coarctation will generally not survive without intervention.

7 Older children with coarctation are usually asymptomatic. The diagnosis is commonly made on the basis of hypertension in the upper extremities with decreased pulses in the lower extremities. Noninvasive blood pressure measurements in all four extremities help to quantify the severity of aortic obstruction. These older patients tend to develop extensive collateral arteries that bypass the obstruction. Life expectancy for these patients is limited due to the development of heart failure later in life. Other long-term complications of coarctation include chronic hypertension, endocarditis (frequently involving a bicuspid aortic valve), endarteritis (in the poststenotic area of the aorta at the site of the jet of turbulent flow), aortic dissection, aortic aneurysm, and intracranial hemorrhage (from Berry aneurysms, which occur more commonly in patients with coarctation).¹⁰⁵

The diagnosis of coarctation can usually be made clinically. The infant with significant coarctation is frequently asymptomatic at birth, but following closure of the ductus develops

signs of heart failure such as irritability, tachypnea, and poor feeding. Lower extremity pulses are absent, and upper extremity pulses may be weak. Chest radiography shows cardiomegaly and pulmonary venous congestion. There is a left ventricular strain pattern on the ECG. Echocardiography is usually diagnostic, demonstrating narrowing of the aorta at the coarctation site with a loss of pulsatility in the descending aorta.

In older children and adults with coarctation, there is usually a pressure gradient between the arms and legs, which can be demonstrated by measuring cuff pressures in all four extremities. On chest radiography, rib notching may be evident, secondary to erosion of the inferior rib borders from the development of large intercostal collateral vessels. Echocardiography usually confirms the diagnosis. Anatomic details may also be clarified with computed tomography (CT) and MRI. Cardiac catheterization is usually not necessary.

Generally, all patients with coarctation should undergo surgical repair. For neonates, the acute medical management includes initiation of PGE₁ for the purpose of reopening the ductus; this maneuver partially relieves the aortic obstruction and augments perfusion of the lower body due to improved antegrade flow across the arch, as well as right-to-left flow across the ductus. Prostaglandins are usually effective for reopening the ductus when initiated within 7 to 10 days of life, but are less successful thereafter.

Surgical repair of coarctation is usually performed through a left posterolateral thoracotomy via the third or fourth intercostal space. Neonates with an associated hypoplastic aortic arch may require sternotomy for extended arch augmentation with either primary extended end-to-end repair or patch augmentation. For repair via thoracotomy, the descending thoracic aorta, ductus (or ligamentum), transverse aortic arch, and brachiocephalic vessels are mobilized. Care is taken to preserve the vagus nerve and its recurrent laryngeal branch. The preferred surgical approach to coarctation in infants and children is a resection with end-to-end anastomosis or extended end-to-end repair if there is associated mild distal arch hypoplasia.¹⁰⁶ In older children and adults, it may not be possible to perform a resection with primary repair without creating excessive tension on the anastomosis, which may lead to hemorrhage or scarring with recurrent coarctation. An alternative strategy is necessary in these cases. Patch aortoplasty may be performed in children in whom further growth is anticipated.^{107,108} The subclavian flap repair augments the narrowed aorta using native arterial tissue. Blood flow to the left arm is maintained by collateral vessels, although long-term studies have demonstrated a slight discrepancy in limb length in some patients. Prosthetic patch material may also be used. By avoiding circumferential prosthetic material, growth potential of the native aorta is preserved. The disadvantage of patch repair is a high risk of aneurysm formation. In adults, in whom growth is no longer a concern, resection of the coarctation may be performed with subsequent placement of a prosthetic interposition graft (either Dacron or polytetrafluoroethylene).

One of the principal concerns during coarctation repair is interruption of distal aortic blood flow, especially to the spinal cord. The anterior spinal artery is fed by major radicular branches from intercostal arteries. In patients without well-formed collaterals, ischemia of the spinal cord may be precipitated by aortic cross-clamping, and paraplegia may result. Protective measures include induction of mild hypothermia, maintenance of a high proximal aortic pressure, and minimization of cross-clamp time. In older patients, distal aortic perfusion may be maintained by the technique of left heart bypass, in which oxygenated blood is taken from the left atrium and delivered to the femoral artery or distal aorta using a centrifugal pump.¹⁰⁹ This is usually not necessary due to the presence of significant collaterals. Overall, the incidence of paraplegia following coarctation repair is less than 1%.¹¹⁰

Following repair, patients may develop severe hypertension. This can be managed using intravenous beta-blockers (e.g., esmolol). Uncontrolled hypertension can lead to the complication of mesenteric arteritis. Hypertension usually resolves within days to weeks after repair, although older children and adults may require lifelong antihypertensive therapy. Repair of coarctation during infancy is thought to minimize the risk of late hypertension.¹¹¹

Transcatheter intervention for primary therapy of discrete coarctation in young children and adolescents remains controversial. Technical success rates range from 80% to 98%, with reintervention rates of 10% to 20%.^{112–114} Placement of a stent has been associated with higher success rates and lower restenosis rates¹¹⁴; however, the long-term outcome of stents in this population remains unknown, and stents are not an ideal option in younger children. There is no evidence to date, therefore, that demonstrates superiority or equivalence of catheter intervention compared to surgery. In addition, there is a high complication rate of 5% to 11.7%, including recurrent coarctation, need for multiple interventions, injury to the femoral vasculature (for access), aortic dissection, and aneurysm formation.^{113,115–117} On the other hand, balloon angioplasty is widely accepted for the treatment of recurrent coarctation following surgery, in which the success rate is on the order of 90% with low recurrence rates.^{118–120}

The early mortality following repair of coarctation in neonates is 2% to 10%, whereas the risk in older children and adults is about 1%.^{106,121} The incidence of recurrent coarctation following resection and end-to-end repair is about 4% to 8%.^{106,122,123} The long-term survival following repair of coarctation is determined by the presence of associated defects and the persistence of hypertension.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a normal fetal vascular structure that allows blood from the right ventricle to bypass the high-resistance pulmonary vascular bed and pass directly to the systemic circulation. The ductus communicates between the main PA (or proximal left PA) and the proximal descending thoracic aorta. Histologically, the media of the ductus contains a predominance of smooth muscle cells, whereas the media of the aorta and PA contain well-developed elastic fibers. Vasoconstriction of the ductus is mediated by two important mechanisms: oxygen tension and prostaglandin levels. During fetal development, low oxygen tension and high levels of circulating prostaglandin maintain ductal patency. During the final trimester, the ductus becomes less sensitive to prostaglandins and more sensitive to the effects of oxygen tension. Following birth, the rise in oxygen tension and a fall in prostaglandins (which were previously supplied principally by the placenta) lead to ductal closure, which is usually complete by 12 to 24 hours. After closure, the ductus becomes a fibrous cord known as the ligamentum arteriosum. Failure of closure of the ductus leads to the condition called patent ductus arteriosus. PDA occurs in about 1 out of 1,200 live births and accounts for 7% of congenital heart defects.⁷ The incidence is much higher in premature infants (>20%).¹²⁴ This elevated incidence is thought to be related to immaturity of the ductal wall resulting in impaired sensitivity to oxygen tension.

PDA may occur as an isolated defect, or it may occur in association with a number of other anomalies. Patency of the ductus arteriosus is desirable in a number of defects in which there is either inadequate PBF (such as pulmonary atresia) or inadequate systemic blood flow (as in severe coarctation of the aorta). The discovery that extrinsic delivery of prostaglandins can maintain ductal patency has played a critical role in improving the survival of these patients.¹²⁵

The physiologic manifestation of PDA is shunting of blood across the ductus. The shunt volume is determined by the size

of the ductus and by the ratio of pulmonary to systemic vascular resistance. At birth, the PVR drops dramatically and continues to decline over the first several weeks of life. As a result, shunting across a PDA is from left to right. Excessive PBF can lead to CHF. In extreme cases, hypotension and systemic malperfusion may result. Patients with a large PDA who survive infancy tend to develop pulmonary vascular obstructive disease. Eisenmenger physiology results when the PVR exceeds the systemic vascular resistance, producing a reversal of shunting across the ductus to right to left. This leads to cyanosis and, eventually, right ventricular failure. Small PDAs may persist to adulthood without producing any symptoms or physiologic derangement. Endocarditis and endarteritis have been reported as long-term complications of PDA.¹²⁶

In patients with PDA, symptoms are proportional to the shunt volume and the presence of associated defects. Left-to-right shunting produces volume overload of the left heart. Infants with CHF demonstrate symptoms of tachypnea, tachycardia, and poor feeding. Older children may present with recurrent respiratory infections, fatigue, and failure to thrive. Physical findings include a widened pulse pressure and a continuous “machinery” murmur heard best along the left upper sternal border. Chest radiography shows increased pulmonary vascular markings and left heart enlargement. Left ventricular hypertrophy and left atrial enlargement may be evident on the ECG. Echocardiography is the diagnostic method of choice. Diagnostic cardiac catheterization is performed only in older patients with suspected pulmonary hypertension to evaluate for pulmonary vascular obstructive disease. More frequently, catheterization is utilized for transcatheter occlusion of the ductus in selected cases.

PDA closure is performed for all symptomatic patients. Closure is also recommended for asymptomatic patients due to the risk of heart failure, pulmonary hypertension, and endocarditis. Closure of the ductus may be accomplished by one of three approaches: pharmacologic, surgical, and endovascular. Indomethacin and ibuprofen, which are cyclooxygenase inhibitors, stimulate PDA closure in premature infants.^{127,128} Both are rarely effective in full-term infants. Due to improved side effect profile of gastrointestinal bleeding and renal dysfunction, ibuprofen is the current drug of choice.¹²⁸ The dosing regimen is 10 mg/kg intravenously, followed by 5 mg/kg intravenously at 24-hour intervals for a total of three doses. This is effective in about 70% to 80% of premature babies.^{128,129} Due to their side effects, indomethacin and ibuprofen are contraindicated in patients with sepsis, renal insufficiency, intracranial hemorrhage, or bleeding disorders. Failure of ibuprofen after two complete courses results in referral for surgical closure.

The surgical approach to PDA is through a left posterolateral thoracotomy via the third or fourth intercostal space. The pleura is incised over the proximal descending thoracic aorta. This allows medial retraction of the vagus nerve. The recurrent laryngeal nerve curves behind the ductus and should be protected throughout the procedure. Dissection is then performed to demonstrate the pertinent anatomy. In many cases, the ductus is the largest vascular structure present, and it must not be confused with the aorta. Ductal tissue is extremely friable, so direct manipulation is minimized. In premature infants, the ductus is controlled with a single surgical clip; this procedure is commonly performed in the neonatal intensive care unit, thereby avoiding problems associated with patient transfer.^{130,131} In older patients, occlusion of the ductus is achieved with simple silk ligature, or, preferably, by division between ligatures to minimize recurrence.

Thoracoscopic techniques have been developed to perform PDA ligation.¹³² This approach has the potential benefits of decreased pain and quicker recovery. Disadvantages include a substantial learning curve and increased operating time.

A number of endovascular devices have been developed for the purpose of transcatheter occlusion of the PDA.^{133–135} This

approach is very successful in older infants, children, and adults with small and moderate-sized PDAs and has become the treatment of choice at many centers. Surgical therapy is reserved for PDAs having a large diameter or very short length.

Rarely, an adult will present with a significant PDA. These patients must be carefully evaluated for the presence of pulmonary vascular obstructive disease prior to ductal closure. If the patient is not a candidate for device closure, surgical closure can be problematic. Calcification of the ductal wall is common in adults, making ligation hazardous. In some cases, cardiopulmonary bypass may be required with closure of the ductus from within the PA.^{136,137}

Closure of the ductus by surgical or transcatheter techniques is achieved with a mortality that approaches zero.¹³⁰ Potential complications include pneumothorax, phrenic nerve injury, recurrent laryngeal nerve injury, and chylothorax (from injury to the thoracic duct). Long-term survival should be normal following PDA ligation in most patients. Survival in premature infants depends primarily on the extent of prematurity with its attendant complications.

VASCULAR RINGS

Vascular rings comprise a spectrum of vascular anomalies of the aortic arch, pulmonary artery, and brachiocephalic vessels. The clinically significant manifestation of these lesions is a varying degree of tracheoesophageal compression. These vascular anomalies can be divided into complete vascular rings and partial vascular rings. Incomplete vascular rings include aberrant right subclavian artery, innominate artery compression, and pulmonary artery sling. The incidence of clinically significant vascular rings is 1% to 2% of all congenital heart defects.⁷

Vascular rings and pulmonary slings have been described in conjunction with other cardiac defects, including tetralogy of Fallot, atrial septal defect, branch pulmonary artery stenosis, coarctation, atrioventricular septal defect, ventricular septal defect, interrupted aortic arch, and aortopulmonary window. Significant associated cardiac anomalies occur in 11% to 20% of patients with a vascular ring.^{138,139} A right aortic arch is generally associated with a greater incidence of coexisting anomalies.

By the end of the fourth week of embryonic development, the six aortic or branchial arches have formed between the dorsal aortae and ventral roots. Subsequent involution and migration of the arches results in the anatomically normal or abnormal development of the aorta and its branches. The majority of the first, second, and fifth arches regress. The third arch forms the common carotid artery and proximal internal carotid artery. The right fourth arch forms the proximal right subclavian artery. The left fourth arch contributes to the portion of the aortic arch from the left carotid to left subclavian arteries. The proximal portion of the right sixth arch becomes the proximal portion of the right pulmonary artery, while the distal segment involutes. Similarly, the proximal left sixth arch contributes to the proximal left pulmonary artery, and the distal sixth arch becomes the ductus arteriosus.

Children with a complete vascular ring generally present within the first weeks to months of life. Typically, children with a double aortic arch present earlier in life than those with a right arch and retroesophageal left ligamentum. In the younger age group, respiratory symptoms predominate, as liquids are generally well tolerated. Respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections. The cough is classically described as a “seal bark” or “brassy.” These symptoms may mimic asthma, respiratory infection, or reflux, and children with vascular rings are often initially misdiagnosed. With the transition to solid food, dysphagia becomes more apparent.

The presentation of a patient with an incomplete vascular ring is variable. Children with innominate artery compression usually present within the first 1 to 2 years of life with respiratory symptoms. Aberrant right subclavian artery is the most common arch abnormality, occurring in approximately 0.5% to 1% of the population, and it rarely causes symptoms. Classically, when symptoms do occur, they present in the seventh and eighth decades, as the aberrant vessel becomes ectatic and calcified, causing *dysphagia lusoria* due to impingement of the artery on the posterior esophagus.

Children with pulmonary artery slings generally present with respiratory symptoms within the first few weeks to months of life. As with complete rings, respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections and may mimic other conditions, leading to misdiagnosis. Pulmonary artery slings are associated with complete tracheal rings in 30% to 40% of patients, leading to focal or diffuse tracheal stenosis.

The methods for diagnosing a vascular ring are variable, due to the variability in presentation and the spectrum of diagnostic tests available. A child with a presumptive diagnosis of asthma or tracheomalacia may be referred to a pulmonologist and a diagnosis of vascular ring made or suspected initially by chest radiograph and bronchoscopy. In some situations, the diagnosis is made by echocardiography during evaluation for concurrent cardiac defects. Regardless, the diagnosis generally begins with a chest radiograph. Complementary studies may include barium esophagogram, CT, MRI, and bronchoscopy. CT, MRI, and bronchoscopy are important modalities to define the tracheal anatomy in a patient with a pulmonary artery sling. Echocardiography may be diagnostic, and may be used to rule out other cardiac anomalies. Tracheograms and cardiac catheterizations, which have been used extensively in the past, are rarely currently indicated.

A double aortic arch occurs when the distal portion of the right dorsal aorta fails to regress. The two arches form a complete ring, encircling the trachea and esophagus. The right arch is dominant in the majority of the cases, followed by left dominant, with codominant arches being the least common. The left and right carotid and subclavian arteries generally arise from their respective arches. The ligamentum arteriosum and descending aorta usually remain on the left.

The approach to repair of a double aortic arch is via a left posterolateral thoracotomy. The pleura is incised, after identifying the vagus and phrenic nerves. The ligamentum or ductus arteriosum is divided while preserving the recurrent laryngeal nerve. The nondominant arch is then divided between two vascular clamps at the point where brachiocephalic flow is optimally preserved. If there is concern regarding the location for division, the arches can be temporarily occluded at various points while monitoring pulse and blood pressure in each limb. If there is an atretic segment, the division is done at the point of the atresia. Dissection around the esophagus and trachea in the regions of the ligamentum/ductus and nondominant arch allows for retraction of the vascular structures and lysis of any residual obstructing adhesions.

The surgical approach for a right aortic arch with retroesophageal left ligamentum arteriosum is the same as for a double arch. The ligamentum is divided and any adhesions around the esophagus and trachea are lysed. Rarely, the Kommerell diverticulum has been reported to cause compression even after division of the ligamentum. As such, it may be prudent to resect or suspend the diverticulum posteriorly.

In innominate artery compression syndrome, the aortic arch and ligamentum are in their normal leftward position. However, the innominate artery arises partially or totally to the left of midline. As the artery courses from left to right anterior to the trachea, it causes tracheal compression. The symptoms of innominate artery compression may be mild to severe. With mild symptoms and minimal tracheal compression on bronchoscopy, children can be observed expectantly as the

symptoms may resolve with growth. Indications for surgery include apnea, severe respiratory distress, significant stridor, and recurrent respiratory tract infection. Several approaches for the correction of innominate artery compression syndrome have been described. These include simple division, division with reimplantation into the right side of the ascending aorta, and suspension to the overlying sternum.

An aberrant right subclavian artery occurs when there is regression of the right fourth arch between the right common carotid and right subclavian arteries. The right subclavian then arises from the leftward descending aorta, laying posterior to the esophagus as it crosses from left to right. Although the artery can compress the esophagus posteriorly, it is rarely the cause of symptoms in children. Surgical treatment involves simple division via a left posterolateral thoracotomy. Rarely, reimplantation or grafting from the right carotid or aortic arch may be necessary.

Normally, the right and left sixth aortic arches contribute to the proximal portions of their respective pulmonary arteries. If the proximal left sixth arch involutes and the bud from the left lung migrates rightward to meet the right pulmonary artery, a pulmonary artery sling is formed. Pulmonary artery slings are associated with complete tracheal rings and tracheal stenosis in 30% to 40% of patients.

Initial attempts at the repair of a pulmonary artery sling involved reimplantation after division of the left pulmonary artery (LPA) and translocation of the trachea without cardiopulmonary bypass. These early reports had a high incidence of LPA thrombosis. This has led some authors to advocate division of the trachea and translocation of the LPA. This approach would seem sensible if the trachea were being divided in the course of tracheal reconstruction. However, currently most authors advocate the reimplantation of the LPA, which has resulted in excellent results. The procedure is done via a median sternotomy on cardiopulmonary bypass to ensure optimal visualization of the repair. Aortic cross-clamping is not necessary. The LPA is divided off of the right pulmonary artery, translocated anterior to the trachea, and reimplanted into the main pulmonary artery.

Any necessary reconstruction of the trachea is done concurrently with bronchoscopic assistance. Many techniques for tracheal reconstruction have been described, the most common of which are resection with primary reanastomosis and sliding tracheoplasty for short-segment stenosis, and rib cartilage or pericardial patch for long areas of narrowing.¹⁴⁰

Over 95% of vascular rings without concurrent cardiac defects can be performed through a left thoracotomy. A right thoracotomy is indicated for the rare cases where there is a right ligamentum arteriosum. In addition, a double aortic arch with an atretic segment proximal to the right carotid artery is more easily divided through a right thoracotomy. The approach to these anomalies is the same as for a left-sided ring division, with the caveat that the right recurrent laryngeal nerve will loop around the right ligamentum.

Repair of vascular rings has been described using video-assisted thoracoscopic surgery (VATS) both with and without robotic assistance. Candidates for thoracoscopic division are limited to those patients requiring only the division of non-patent vascular structures. In general, VATS is used for patients greater than 15 kg due to current size limitations of the instruments.¹⁴¹

Mortality for the repair of a vascular ring is 0% to 4%, with improved survival occurring in more recent series.^{138,139,142} The majority of deaths are related to other cardiac defects or respiratory infection and failure. Backer et al. reported a series of 16 patients repaired utilizing LPA division and reimplantation for pulmonary artery sling, all of whom also required tracheal reconstruction. There were no operative mortalities and one late death due to respiratory complications.¹⁴⁰ The major source of morbidity, as well as

mortality, in this and other series is related to the tracheal reconstruction.

CORONARY ARTERY ANOMALIES

Coronary artery anomalies occur in 0.3% to 1.3% of the population.^{143,144} They can be classified as minor, secondary, or major based on their clinical significance.¹⁴⁵ Minor defects have no functional significance and are usually detected as incidental findings at cardiac catheterization. Secondary defects have no intrinsic significance, but alter surgical management when they are present. An example of a secondary defect is an anomalous origin of the left anterior descending artery from the right coronary artery that crosses the hypoplastic infundibulum in a patient with TOF. The presence of this vessel may prevent the safe performance of a transannular incision and thereby mandate the use of a conduit. Major defects are the most important form of coronary anomaly, because they exert an intrinsically adverse effect on the myocardium. Major anomalies can be subdivided based on anatomy: coronary arteriovenous fistula, anomalous pulmonary origin of a coronary artery, anomalous aortic origin of a coronary artery, myocardial bridging, or coronary artery aneurysm.

8 Coronary arteriovenous fistula is the most common major coronary anomaly. An abnormal connection exists between a coronary artery (usually the right) and another vascular structure (usually one of the right heart chambers). Most fistulas are isolated and solitary. The fistula leads to left-to-right shunting, which can produce CHF. Other symptoms include angina, endocarditis, myocardial infarction, arrhythmia, and sudden death. The diagnosis is suggested by echocardiography and confirmed by catheterization. All symptomatic fistulas should be occluded, either surgically or by transcatheter techniques. In some cases, coronary bypass grafting may be necessary when distal flow is compromised by fistula occlusion. Treatment of asymptomatic fistulas is controversial, but occlusion should probably be undertaken when significant left-to-right shunting is present.

The second most common major coronary anomaly is origin of a coronary artery from the PA. The most common manifestation is the anomalous left coronary artery arising from the pulmonary artery (ALCAPA). The right coronary (or both coronaries) may also arise anomalously from the PA, but only in very rare cases. ALCAPA is usually well tolerated during fetal development, but after birth, the pulmonary systolic pressure usually drops (following ductal closure and decline in PVR) and the anomalous coronary is perfused with desaturated blood at low pressure. Collateral vessels develop between the normal right coronary artery and the abnormal left coronary, but the benefit is negated due to the development of coronary steal, whereby the collateral blood shunts left to right by retrograde flow in the anomalous coronary into the low-pressure PA. Most patients will present between 6 weeks and 3 months of life. Typical symptoms include irritability, difficulty in feeding, and other signs of CHF. Untreated, ALCAPA is nearly always fatal. Rarely, patients will survive to adulthood and present with symptoms of angina or sudden death. On examination, patients with ALCAPA frequently have a holosystolic murmur of ischemic mitral regurgitation. The pulmonary component of the second heart sound may be pronounced due to pulmonary hypertension. Chest radiography is significant for cardiomegaly and pulmonary edema. Electrocardiographic evidence of ischemia and infarction is usually present. Echocardiography is usually diagnostic and is useful for assessing the severity of left ventricular dysfunction and ischemic mitral regurgitation, which are commonly present. Catheterization is occasionally necessary to clarify the anatomy, but this technique is used less frequently due to the risk of inducing life-threatening arrhythmias.

Surgical repair is indicated for all patients with ALCAPA. Historically, the initial surgical approach involved ligation of the proximal left coronary artery. This served to eliminate coronary steal and allow perfusion of the left coronary system by collaterals from the right. Despite the ease of simple ligation, most centers have abandoned this approach in favor of establishment of a two-coronary system, which offers better long-term freedom from ischemia. In older patients, this may be achieved by proximal ligation of the left coronary artery in conjunction with coronary artery bypass, ideally with a left internal mammary graft. Coronary bypass is technically difficult in neonates, and a number of alternative operations have been devised to create a direct connection between the aorta and the anomalous coronary artery. Most commonly, this can be achieved by removing the origin of the left coronary artery (along with a button of adjacent PA) and reimplanting the vessel directly into the side of the aorta. Another approach involves creation of a side-to-side connection between the aorta and PA with placement of an intrapulmonary baffle to direct flow from this connection to the anomalous left coronary ostium. With improved coronary transfer techniques learned from the arterial switch operation, direct reimplantation of the anomalous coronary artery is always feasible and preferred. Survival following surgical repair of ALCAPA has improved over the years.¹⁴⁶ Recent reports have suggested an operative mortality of 6% or less.^{147,148} Ventricular function tends to normalize after surgery.¹⁴⁹ In most patients, mitral valve function also improves,^{147,149} but for patients with severe mitral regurgitation, concurrent mitral valve repair may rarely be indicated.

Anomalous aortic origins of the coronary arteries are usually minor defects, but a potentially dangerous abnormality exists when the left main coronary artery arises from the right coronary sinus and passes between the PA and aorta. This defect has been associated with cardiac symptoms and sudden death, as has the origin of the right coronary artery from the left coronary sinus (usually when the right coronary is dominant).^{150,151} The etiology of ischemia in both defects is thought to be related to the acute angle of origin and slitlike orifice of the anomalous vessel often with an intramural course and the extrinsic compression created by the opposing walls of the aorta and PA. These defects usually present in older patients. Symptomatic patients are treated surgically by unroofing the coronary ostia into the aorta or by coronary artery bypass.

Myocardial bridging occurs when a segment of an epicardial coronary artery (usually the left anterior descending) takes an intramyocardial course over a short segment. Although this is a common incidental finding at cardiac catheterization, this defect has been associated in some cases with myocardial ischemia. Treatment involves dividing the muscle bridge to free the coronary, coronary bypass beyond the bridge, or transcatheter stenting.

Coronary aneurysms occur rarely, usually in conjunction with an inflammatory condition such as Kawasaki syndrome, polyarteritis nodosa, Takayasu arteritis, or syphilis. Coronary aneurysms may thrombose or lead to distal coronary stenosis or embolization. Rupture occurs uncommonly. Treatment ranges from antiplatelet therapy to coronary bypass grafting.

UNIVENTRICULAR HEART

In the univentricular heart, only one ventricular chamber is connected to the atria. To be classified as a ventricle, a chamber must receive at least half of an inlet valve. In the most common form of univentricular heart, both the mitral and tricuspid valves connect to a morphologic LV (double-inlet LV), which ejects blood through a hypoplastic outlet chamber and

then, due to malposition of the great arteries, to the aorta. The outlet chamber is not considered to be a ventricle, regardless of its size, because it does not receive an inlet valve. Similarly, the intracardiac communication is not termed a VSD, but a bulboventricular foramen. Univentricular hearts are frequently associated with malpositions of the great vessels and varying degrees of obstruction to PBF. In double-inlet LV, the aorta is usually anterior and to the left of the PA.

The presentation of infants with univentricular heart is variable, depending on the amount of PBF.¹⁵² When the pulmonary flow is excessive, cyanosis may be mild, and the dominant feature is CHF. Associated PS decreases the PBF, and the degree of cyanosis is increased. Associated lesions may further complicate the picture, such as coarctation, subaortic stenosis, or a restrictive ASD. Patients with moderate PS may achieve a well-balanced circulation with acceptable systemic oxygenation and normal PA pressure. These patients may be symptom-free well into adolescence. Most patients, however, require intervention early in life to reduce excessive PBF or to increase it in the presence of significant PS. Pulmonary vascular obstructive disease develops early when PBF is excessive. With the possible exception of patients in whom the pulmonary and systemic blood flow is well balanced, the prognosis for patients with unoperated univentricular hearts is poor, with more than half dying early of CHF or dysrhythmias.

In the presence of excessive PBF and pulmonary hypertension, operation should be performed early in life to control PBF and prevent the development of pulmonary vascular occlusive disease. Options include PA banding or division of the main PA in conjunction with a controlled aortopulmonary shunt. PA banding is a less complicated procedure; however, it is often difficult to adjust the pulmonary flow accurately, and too proximal or too distal a band can lead to distortion of the pulmonary valve or branch pulmonary arteries, which further complicates later operations. Simple division of the PA with placement of a modified Blalock-Taussig shunt can be undertaken in the presence of an adequate bulboventricular foramen providing unobstructed flow to the aorta. This option avoids the problems associated with a PA band, and more accurately controls the PBF. Another similar technique is division of the main PA, side-to-side anastomosis of the proximal PA with the native aorta, and placement of a modified Blalock-Taussig shunt (modified Damus-Kaye-Stanzel procedure). It is not uncommon for the bulboventricular foramen to decrease in size over time due to progressive ventricular hypertrophy. Maintaining continuity from both the outlet chamber and the LV eliminates the possibility of subaortic obstruction, which can occur when the systemic blood flow depends entirely on egress through a bulboventricular foramen. In infants who are well balanced and can be safely managed medically until the age of 4 to 6 months, a hemi-Fontan or bidirectional Glenn, in which the superior vena caval flow is directed into the pulmonary arteries, can be used to increase the effective PBF. This procedure maximizes pulmonary flow without causing a volume overload to the single ventricle. It is most commonly used as part of an interim stage to a complete atriopulmonary connection or Fontan procedure.

The ultimate goal of surgical correction in patients with a univentricular heart is the total diversion of all vena caval blood directly into the pulmonary arteries. The Fontan procedure was first successfully performed in a patient with tricuspid atresia, but has since evolved as an excellent way to establish physiologic repair for patients with more complex forms of univentricular heart.¹⁵³ The superior vena caval blood returns directly via an end-to-side anastomosis with the PA (bidirectional Glenn) or through a right atrial-PA connection (hemi-Fontan). The inferior vena caval flow is directed to the PA with an intra-atrial baffle (lateral tunnel technique, Fig. 81.10) or an extracardiac conduit. All oxygenated pulmonary venous flow empties into the ventricular chamber through the

FIGURE 81.10. Total cavopulmonary connection for univentricular heart. The internal orifices of the superior and inferior venae cavae are connected in the right atrium with a patch cut of polytetrafluoroethylene. The superior vena cava is divided just above its junction with the right atrium, and both ends are anastomosed to the right pulmonary artery. The main pulmonary artery is ligated.

AV valves to be ejected to the systemic circulation, while superior and inferior vena caval blood flows directly to the lungs to acquire oxygen prior to returning to the heart. For the Fontan procedure to be performed with a low operative mortality and an acceptable functional result, certain criteria must be met. Normal PA pressure (<20 mm Hg) and PVR (<2 Woods units/ m^2) are the most important prerequisites. Additionally, it is essential that ventricular function and AV valve function be normal. Many of the criteria originally proposed, including normal cardiac rhythm, right atrial hypertrophy, normal systemic venous return, and age older than 4 years, are of little or no importance in the current era. Although the Fontan procedure cannot be considered a truly corrective operation, it offers benefits that cannot be equaled by any of the other palliative procedures. The major advantages include restoration of normal systemic oxygen saturation and reduction of ventricular volume overload.

Ventricular septation procedures have also been successfully performed in patients with univentricular hearts. The subset of patients with a double-inlet LV, anterior and leftward aorta, nonrestrictive outlet foramen, and mild or no PS are best suited for septation. This anatomy allows placement of a relatively direct and straight prosthetic patch in the ventricle that separates the pulmonary and systemic circulations. The septation procedure has been associated with a relatively high morbidity, primarily related to complete heart block, so that its overall effectiveness is reduced. Few

centers have continued to apply this procedure in carefully selected patients.

The current results for the Fontan are excellent, with hospital mortality ranging from 2% to 9%.^{154–158} The condition of survivors is generally good and most attain a functional status of New York Heart Association class I or II. The long-term results have been reported with a 93% to 97% 5-year survival and a 91% 10-year survival.^{156,157} Although long-term results are encouraging, late complications may be seen. Continued surveillance for arrhythmias, CHF, protein-losing enteropathy, and hepatic dysfunction remains important.

HYPOPLASTIC LEFT-HEART SYNDROME

Hypoplastic left-heart syndrome (HLHS) refers to a constellation of congenital cardiac anomalies characterized by marked hypoplasia or absence of the LV and severe hypoplasia of the ascending aorta. The systemic circulation is dependent on the right ventricle via a PDA and there is obligatory mixing of pulmonary and systemic venous blood in the right atrium. There is associated aortic valve stenosis or atresia, and mitral valve stenosis or atresia. The descending aorta is essentially a continuation of the ductus arteriosus, and the ascending aorta and aortic arch are a diminutive branch from this vessel. Initial management includes a prostaglandin infusion to maintain ductal patency and correction of metabolic acidosis. The patient may require intubation and ventilator adjustment to reduce supplemental oxygen and maintain a partial pressure of carbon dioxide (PCO_2) of about 40 mm Hg to avoid excessive pulmonary flow.

Treatment options for this problem include cardiac transplantation and staged reconstructive surgery. Transplantation for HLHS is generally performed with the same techniques that are standard for transplantation in older children and adults. However, it is necessary to have a generous amount of donor aortic arch that can be used to augment the hypoplastic recipient arch. Results of transplantation in neonates have been excellent in centers with extensive experience in this area, and a 2-year survival as high as 70% has been reported.¹⁵⁹ In the context of improving results for staged reconstruction, risks of immunosuppression, and limited donor availability, competing risk analysis favors staged repair, and most centers pursue this option as primary therapy for HLHS.¹⁶⁰ Transplantation is generally reserved for very high-risk patients, such as those with depressed right ventricular function or severe tricuspid regurgitation.

The first successful palliation of HLHS was reported by Norwood et al. on a series of infants operated on between 1979 and 1981.¹⁶¹ This procedure has been technically refined over the years, but three essential components remain: atrial septectomy, anastomosis of the proximal PA to the aorta with homograft augmentation of the aortic arch, and aortopulmonary shunt or right ventricle–PA conduit (Fig. 81.11). As described previously for the univentricular heart, subsequent reconstructive management of HLHS includes an interim hemi-Fontan procedure or bidirectional Glenn anastomosis at 4 to 6 months of age, followed by a Fontan procedure at about 18 to 24 months.

Universally fatal only two decades ago, tremendous strides have been made in improving the outcomes for patients with HLHS. Of the three stages, the highest-risk stage of the repair remains the Norwood operation. During the 1990s, the hospital survival for the Norwood procedure across the United States was approximately 40%.¹⁶² Currently, select centers have reported hospital survivals of 90% or greater.^{163–167} Reported survivals for the hemi-Fontan and Fontan procedures have also been excellent at 98% for both operations.^{155,157,168}

CHAPTER 82 ■ VALVULAR HEART DISEASE AND CARDIAC TUMORS

TOMISLAV MIHALJEVIC, CRAIG M. JARRETT, AND A. MARC GILLINOV

KEY POINTS

- 1 The most common cause of aortic stenosis is degenerative calcific disease, followed by congenital aortic stenosis due to bicuspid valve anatomy.
- 2 Two-dimensional echocardiography with Doppler allows precise real-time analysis of valvular anatomy and function, and is the study of choice for the diagnosis and management of valvular lesions.
- 3 The current indication for cardiac catheterization in patients with valvular heart disease is limited to preoperative evaluation of coronary artery disease.
- 4 There is no effective medical therapy for patients with severe aortic stenosis. Mechanical relief of the obstruction to blood flow is the only effective treatment.
- 5 The most common causes of aortic regurgitation include bicuspid valve disease, rheumatic fever, and endocarditis.
- 6 Mitral stenosis is almost exclusively caused by rheumatic fever.
- 7 The most common cause of mitral regurgitation is degenerative mitral valve disease. Other causes include rheumatic valve disease, endocarditis, certain drugs, and collagen vascular diseases.
- 8 The most common cardiac tumors are secondary tumors, which usually originate from the lung in men and from the breast in women.

VALVULAR HEART DISEASE

Valvular Anatomy

The basic structural framework of all heart valves is provided by the fibrous cardiac skeleton (Fig. 82.1). The skeleton is a collection of dense connective tissue in the shape of four interconnected rings in the plane between the atria and the ventricles. The interconnecting areas include the right fibrous trigone, which is between the aortic and tricuspid rings and contiguous with the membranous septum, and the left trigone and fibrous continuity, which are between the aortic and mitral rings and form the posterior wall of the left ventricular (LV) outflow tract. The cardiac skeleton maintains the integrity of the valve orifices and provides points of attachment for the valve leaflets. It also serves as a partition by electrically isolating the atria and ventricles except at the atrioventricular bundle, which passes through the right fibrous trigone near the septal leaflet of the tricuspid valve.

The normal aortic valve (AV) consists of three semilunar leaflets or cusps projecting outward and upward into the lumen of the ascending aorta (Fig. 82.2). The space between the free edge of each leaflet and the points of attachment to the aorta comprise the sinuses of Valsalva. Since the coronary arteries arise from two of the three sinuses, the sinuses and the respective leaflets are named the right coronary, left coronary, and noncoronary (or posterior) sinuses and leaflets.

The properties of the AV ensure minimal obstruction to flow when open and minimal flow reversal when closed. Opening and closing of the valve are passive, as it functions only in response to pressure differences between the left ventricle and aorta during the cardiac cycle. The pressure generated from ventricular contraction forces the valve open, and the subsequent recoil of blood from the aorta fills the sinuses of Valsalva and forces the leaflets closed.

There are two structures in close proximity to the AV and, therefore, susceptible to injury during AV surgery (Fig. 82.2).

First, the anterior leaflet of the mitral valve (MV) is positioned under the commissure between the left and noncoronary leaflets. Second, the left bundle of His is positioned under the commissure between the right and noncoronary leaflets.

In contrast to the simplistic anatomy and passive opening and closing mechanism of the AV, the anatomy and active valve mechanism of the MV are more complex. Indeed, proper functioning of the MV depends on the organized interaction of all components of the MV apparatus, which consists of the leaflets, annulus, LV papillary muscles, and chordae tendineae.

The normal MV consists of two leaflets: the anterior and posterior leaflets. The anterior leaflet is semicircular in shape, extends from the anteromedial aspect of the mitral annulus, and encompasses approximately one third of the annular circumference. The posterior leaflet is rectangular in shape, extends from the posterolateral aspect of the mitral annulus, and encompasses approximately two thirds of the annular circumference. The leaflets are separated from one another at the annulus by the posteromedial and anterolateral commissures. Both leaflets are divided by clefts into three scallops, named laterally to medially A1, A2, and A3, and P1, P2, and P3, and together comprise an average cross-sectional area of 5 to 11 cm².

The mitral annulus is formed anteriorly by the confluence of the right, left, and intervalvular fibrous trigones and posteriorly by a fibrous band. Since the anterior aspect of the mitral annulus is composed of the fibrous trigones, it has limited flexibility. Conversely, the posterior aspect of the annulus, which is not surrounded by any rigid structures, has more flexibility. This increased flexibility of the posterior aspect relative to the anterior aspect has important implications during the cardiac cycle. In systole the mitral annulus contracts (primarily the posterior aspect) and adopts an elliptical shape (shortening occurs perpendicular to the line of leaflet coaptation), and in diastole it relaxes and adopts a circular shape.^{1,2} This dynamic motion of the annulus provides

FIGURE 82.1. Schematic diagram of the fibrous cardiac skeleton.

increased leaflet coaptation during systole and increased orifice area during diastole.

Two papillary muscles arise directly from the ventricular wall: the anterolateral and posteromedial papillary muscles. Importantly, the anterolateral papillary muscle usually is supplied by two coronary arteries, the left anterior descending artery and branches of the circumflex artery. On the other hand, the posteromedial papillary muscle is usually supplied by a single coronary artery, either from the right coronary or the circumflex artery, which makes it twice as likely to rupture from ischemia and infarction as the anterolateral papillary muscle. The papillary muscles play an important role in the proper function of the MV. MV closure and appropriate leaflet coaptation are permitted by

end-diastolic and early systolic lengthening of the papillary muscles.³

Chordae tendineae attach the leaflets to the papillary muscles or directly to the ventricular wall and can be categorized based on the attachments. Primary chordae attach to the leaflets at the free edge to ensure proper coaptation without prolapse or flail. The secondary chordae attach along the line of coaptation and are more prominent on the anterior leaflet. Tertiary chordae arise directly from the ventricle or trabeculae carneae and are only present on the posterior leaflet. Lastly, commissural chordae attach to both leaflets and arise from either papillary muscle.

The structures in close proximity to the MV and, therefore, susceptible to injury during MV surgery include the AV, the atrioventricular node, and the circumflex coronary artery (Fig. 82.3).

FIGURE 82.2. Schematic diagram of the relationship of the aortic valve to the underlying structures.

FIGURE 82.3. Schematic diagram of the relationship of the mitral valve to the underlying structures.

AORTIC STENOSIS

Prevalence and Etiology

1 Aortic stenosis (AS) is the most prevalent valvular heart disease in developed countries. The most common cause of AS is degenerative calcific disease, followed by congenital AS due to bicuspid valve anatomy. Rheumatic AS is becoming exceedingly uncommon in developed countries due to efficient prevention of rheumatic heart disease.

Degenerative Calcific Aortic Stenosis. The most frequent cause of AS is degenerative calcification of the AV. The prevalence of degenerative AS in persons older than 65 years, which is the most commonly affected age group, is 2%.⁴ The degenerative process that leads to stiffening of the aortic leaflets is the result of proliferative and inflammatory changes with lipid accumulation and infiltration of macrophages and T lymphocytes.^{4–9} Fibrosis and calcification initially affect the base of the leaflets, but ultimately progress to immobilization of the leaflets due to large calcific deposits that can extend deep into the annulus. These deposits may also extend onto the ventricular surface of the anterior leaflet of the MV, as well as into the wall of the ascending aorta. The risk factors for the development of calcific AS are similar to those for atherosclerosis and include elevated serum levels of low-density lipoprotein (LDL) cholesterol, diabetes, smoking, and hypertension.^{10,11}

Bicuspid Aortic Stenosis. Calcification of bicuspid AVs, which are present in approximately 2% of the general population, represents the most common form of congenital AS. In patients with bicuspid AVs, the left and right coronary cusps are usually fused, while the noncoronary cusp is freestanding. Gradual calcification of the bicuspid valve results in AS with typical onset of symptoms in the fifth or sixth decade of life, in contrast to degenerative AS, which causes symptoms in elderly individuals. Bicuspid AS is frequently associated with degenerative changes in the wall of the ascending aorta with resultant dilatation or aneurysm formation.

Rheumatic Aortic Stenosis. Introduction of effective antibiotic therapy has resulted in a decline in the prevalence of rheumatic fever and rheumatic valve disease. Rheumatic AS is caused by inflammation and thickening of the AV leaflets,

producing a mixture of AS and regurgitation. Rheumatic AS is rarely an isolated disease, and usually occurs in conjunction with MV stenosis.¹²

Pathophysiology

Regardless of the etiology of AS, the pathophysiologic consequences are similar. Narrowing of the AV to one quarter of its normal area of 3.0 to 4.0 cm² produces a significant pressure gradient between the left ventricle and aorta. There is a resultant increase in LV workload and compensatory LV hypertrophy.

Even though this hypertrophy is an appropriate response to the increased afterload, there are numerous harmful effects. First, the increased wall thickness makes the ventricle stiff and less compliant. This leads to diastolic dysfunction and increased wall tension. In addition to diastolic dysfunction, systolic dysfunction, typically occurring later in the course of the disease, can develop from chronic ischemia. All of the following contribute to increased myocardial oxygen demand: increased LV muscle mass, increased wall tension, increased systolic ventricular pressure, and increased systolic ejection time. There is also decreased coronary artery perfusion, which occurs during diastole, due to increased wall tension, increased diastolic ventricular pressure, and decreased diastolic aortic pressure.^{13,14} The subsequent ischemia of the subendocardium due to increased oxygen demand and decreased perfusion leads to cell death and fibrosis. Chronically, this ischemia results in systolic dysfunction.

Diagnosis

Symptoms. The most common symptoms of AS are angina pectoris, syncope, and heart failure.¹⁵ Angina pectoris occurs in 30% to 50% of patients with severe AS. It is a reflection of myocardial ischemia caused by increased metabolic demands and decreased coronary perfusion. Coronary artery disease, which affects more than 70% of elderly patients with degenerative AV disease, causes further deterioration of myocardial perfusion and lowers the threshold for angina.

Syncope is most commonly due to reduced cerebral perfusion that occurs during exertion. Reduced cerebral perfusion is a result of decreased mean arterial pressure from peripheral vasodilation in the presence of a fixed cardiac output. Approximately 15% of patients present with syncope and only 50% of these survive for 3 years.

Congestive heart failure in patients with severe AS is typically a sign of advanced and longstanding disease. It is marked by shortness of breath and dyspnea with exertion, and results from ongoing LV outflow obstruction. Heart failure is a consequence of the aforementioned diastolic and systolic dysfunction from decreased compliance and ischemia, respectively. In addition, as the left ventricle becomes less compliant, atrial systole becomes more important for maintaining cardiac output and the onset of atrial fibrillation may result in worsening of congestive heart failure.

Some patients with severe AS may develop serious gastrointestinal bleeding secondary to angiodysplasias, occurring predominantly in the right colon, and also in the small bowel and stomach. These result from shear stress-induced platelet aggregation with reduction in high-molecular-weight multimers of von Willebrand factor.

Signs. Signs of AS include a loud systolic ejection murmur that radiates to the neck and is often accompanied by a thrill. “Pulsus parvus et tardus” describes a weak and prolonged arterial pulse characteristic of advanced AS. The weak pulse is a reflection of a narrowed pulse pressure, while the slow rise in pulse reflects a prolonged ejection of blood volume through a stenotic valve.¹⁶

TABLE 82.1 **DIAGNOSIS****CLASSIFICATION OF AORTIC STENOSIS SEVERITY**

■ INDICATOR	■ MILD	■ MODERATE	■ SEVERE
Jet velocity (m/s)	<3.0	3.0–4.0	>4.0
Mean gradient (mm Hg)	<25	25–40	>40
Valve area (cm ²)	>1.5	1.0–1.5	<1.0
Valve area index (cm ² /m ²)			<0.6

**FIGURE 82.5.** St. Jude Medical Regent Valve.

2 **Electrocardiogram and Imaging.** The electrocardiogram typically shows signs of LV hypertrophy, which is found in the majority of patients with AS. Echocardiography represents the “gold standard” modality for the diagnosis of AS. Two-dimensional (2D) echocardiography with Doppler allows precise real-time analysis of ventricular and valvular anatomy and function. The most important objective of echocardiography is correct assessment of the severity of AS using Doppler echocardiography to calculate jet velocity, mean transvalvular pressure gradient, and valve orifice area (Table 82.1). It is also used to assess valve thickening and calcification, as well as reduced leaflet motion. Distinction between bicuspid and tricuspid valves is often possible, particularly when the amount of calcification is small.

Two-dimensional echocardiography is also invaluable in detecting associated MV disease and in assessing LV hypertrophy, systolic function, and diastolic performance. Ejection fraction is used to measure LV systolic function. However, a severe decrease in ejection fraction can falsely lower estimates of severity of AS due to low-pressure gradients. Stress echocardiography with dobutamine administration may be required to properly assess the severity of valvular disease and to distinguish it from primary contractile dysfunction with lack of contractile reserve.¹⁷

3 Cardiac catheterization with direct measurement of the pressure gradients across the AV to calculate the severity of stenosis has been replaced by less invasive echocardiography. The current indication for cardiac catheterization is limited to preoperative evaluation of coronary artery disease.

Natural History

The natural history of AS is marked by a prolonged latent period with few symptoms and minimal morbidity. Even

patients with moderately severe AS have a slow decrease in AV area, generally by approximately 0.1 cm² per year.^{18,19} The natural history of severe AS correlates well with the onset and severity of symptoms. Life expectancy of patients with severe, untreated AS and angina is approximately 5 years. Patients presenting with syncope have life expectancies of 3 years. Presence of congestive heart failure in patients with severe, untreated AS is associated with a worse prognosis, with the time of death occurring less than 2 years from the onset of symptoms (Fig. 82.4).²⁰

Treatment

4 There is no effective medical therapy for patients with severe AS. Diuretics and digitalis may improve the symptoms of congestive heart failure. Mechanical relief of AS is accomplished by surgical AV replacement (AVR), percutaneous AVR, or percutaneous balloon aortic valvotomy.

Surgical Aortic Valve Replacement. The primary indication for surgery is the presence of symptoms in patients with severe AS. AVR is also indicated in patients with severe AS and reduced LV function and in patients with moderate to severe AS who also require coronary, other valve, or aortic surgery.¹⁷ Recent studies suggest that AVR may also be beneficial in patients with asymptomatic severe AS and severe LV hypertrophy.²¹

Choice of valve prosthesis for AVR is primarily influenced by the patient's age. Mechanical prostheses are made of carbon, require lifelong anticoagulation, and are very durable (Fig. 82.5). Mechanical prostheses are therefore indicated in patients younger than 65 years old. Stented biologic prostheses

FIGURE 82.4. Natural history of aortic stenosis without operative treatment. Onset of symptoms identifies patients at high risk of death over the next 2 to 5 years.

FIGURE 82.6. St. Jude Medical Epic Valve.

are most commonly made of bovine pericardium or porcine valve leaflets, do not require anticoagulation, and have a limited durability of approximately 15 years (Fig. 82.6). Biologic prostheses are used in elderly patients (older than 65 years) and in younger patients in whom long-term anticoagulation with warfarin is contraindicated (bleeding diathesis, peptic ulcer disease, etc.).

Percutaneous Aortic Valve Replacement. Percutaneous AVR is a novel form of AVR that uses a bioprosthesis sutured to a balloon-expandable stainless steel or nitinol stent (Fig. 82.7). The prosthesis is introduced through the femoral artery retrogradely into the aorta and placed at the midpart of the native stenotic AV by balloon inflation. The radial forces of the stent push the native AV aside to increase the valve orifice area. In patients with severe peripheral vascular disease, the retrograde arterial approach cannot be used. In these patients, similar prostheses can be inserted directly into the beating heart through the LV apex (transapical approach). Safety and efficacy of percutaneous AVR in high-risk and inoperable patients is currently being evaluated in clinical trials.

Percutaneous Balloon Aortic Valvotomy. Percutaneous balloon aortic valvotomy (PBAV) is a procedure in which a balloon is placed across a stenotic AV and inflated in order to decrease the degree of valve narrowing. This procedure is a valuable tool for treatment of AS in children and young adults. Rapid development of restenosis and clinical deterioration limits its application in the treatment of adults to those with severe AS who are not candidates for conventional surgical AVR.

FIGURE 82.7. Schematic diagram of percutaneous aortic valve replacement. A: Balloon valvuloplasty. B: Balloon catheter with valve in the native diseased valve. C: Balloon inflation to secure the valve. D: Valve in place.

AORTIC REGURGITATION

Prevalence and Etiology

Aortic regurgitation (AR) results from the improper coaptation of the AV leaflets due to either intrinsic leaflet abnormalities or aortic root distortion. The most common causes of AR include bicuspid valve disease, rheumatic fever, and endocarditis. Regurgitant bicuspid AVs are often partly calcified, which results in limited opening and closing of the valve and a mixture of AR and AS. Rheumatic fever causes inflammation and fibrosis of the leaflets, while endocarditis causes destruction of leaflets. In addition, AR can occur as a secondary phenomenon of aortic root enlargement due to Marfan syndrome, anuloaortic ectasia, or aortic dissection. Most of these causes produce chronic AR with a slow increase in LV size. Some lesions, in particular acute aortic dissection and endocarditis, cause acute AR with a sudden decrease in cardiac output.

Pathophysiology

In patients with AR, inappropriate coaptation of the aortic leaflets causes diastolic reflux of blood from the aorta into the left ventricular with a consequent increase in LV end-diastolic volume and pressure. In chronic AR, compensatory mechanisms of the left ventricular result in dilatation and hypertrophy. LV hypertrophy and dilatation ultimately result in a decrease in LV function and heart failure.

Diagnosis

Symptoms. Chronic AR is usually well tolerated and patients with even severe AR often remain asymptomatic for years. Initial symptoms of severe AR include fatigue, shortness of breath, and dyspnea on exertion. Advanced AR is marked by the onset of congestive heart failure, syncope, and angina. Acute onset of severe AR, such as in cases of aortic dissection or endocarditis-induced valve destruction, causes a sudden increase in LV end-diastolic volume and pressure with subsequent cardiogenic shock and pulmonary edema.

Signs. Lateral displacement of the point of maximum impulse is seen in chronic AR due to LV dilation and hypertrophy. The classic auscultatory findings of AR are best heard at the right sternal border of the second intercostal space and include a high-pitched, blowing holodiastolic decrescendo murmur; an S_3 heart sound; and a systolic ejection murmur.

TABLE 82.2

DIAGNOSIS

CLASSIFICATION OF AORTIC REGURGITATION SEVERITY

■ INDICATOR	■ MILD	■ MODERATE	■ SEVERE
Angiographic grade	1+	2+	3–4+
Jet width	<25% LVOT	25%–65% LVOT	>65% LVOT
Regurgitant volume (mL/beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm ²)	<0.10	0.10–0.29	≥0.30

LVOT, left ventricular outflow tract.
Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

Additionally, the widened pulse pressure leads to a number of interesting findings, such as bounding pulses (water-hammer pulse), Quincke pulse (pulse in fingernail bed), De Musset sign (rhythmic bobbing of the head), Duroziez sign (systolic and diastolic murmurs heard over the femoral artery when it is gradually compressed), and Muller sign (pulsations of the uvula).¹⁶

Imaging. Echocardiography represents the diagnostic “gold standard” for patients with AR. It allows assessment of the valvular and aortic anatomy, the severity of regurgitation, and the size and function of the left ventricle. Assessment of the severity of AS is determined by color Doppler jet width, regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 82.2). The role of coronary angiography is reduced to the preoperative diagnosis of coronary artery disease.

Natural History

The natural history of AR is strongly dependent on the presence of symptoms and LV dysfunction at the time of presentation. Asymptomatic patients with normal LV function develop symptoms and/or LV dysfunction at 6% per year. Asymptomatic patients with LV dysfunction at presentation develop cardiac symptoms at 25% per year. Lastly, the mortality rate of symptomatic patients is 10% per year.¹⁷

Treatment

Management of patients with AR depends on the severity of symptoms and the size and function of the left ventricle. Asymptomatic patients with chronic severe AR and preserved LV size and function are treated with vasodilator medical therapy, which reduces afterload and improves forward flow.

Surgery is indicated in symptomatic patients with chronic severe AR and in asymptomatic patients with severe AR and evidence of LV dilatation (end-systolic LV diameter >55 mm) or dysfunction (ejection fraction <50%). Additionally, acute severe AR with consequent pulmonary edema and shock caused by endocarditis or aortic dissection is a surgical emergency.

AVR should be performed before irreversible changes in LV function occur. Mechanical valves are indicated for patients younger than 65 years of age. Stented bioprostheses are used for AVR in patients older than 65 and in younger patients with contraindications to long-term anticoagulation. AV repair can be performed in patients with severe AR caused by bicuspid valve disease or connective tissue disorders. Replacement of the ascending aorta with AV repair is indicated in younger patients with aortic root dilatation and secondary AR.

MITRAL STENOSIS

Prevalence and Etiology

- 6 Mitral stenosis (MS) is predominantly caused by rheumatic fever. The steady rate of decline of rheumatic fever in developed countries has resulted in a similar decline in the prevalence of MS. Other far less common causes of MS include severe annular and leaflet calcification, congenital malformations, malignant carcinoid, left atrial myxoma, left atrial thrombus, and endocarditis. A definitive history of rheumatic fever can only be obtained in 50% to 60% of cases and women are affected more often than men by a 2:1 ratio.^{22,23} Rheumatic fever commonly occurs in childhood or adolescence and can lead to a postinfective pancarditis, affecting to various degrees the valves, endocardium, myocardium, and pericardium. In MS due to rheumatic fever, there is leaflet thickening and calcification, chordal shortening and fusion, and commissural fusion, which all lead to a smaller, funnel-shaped mitral orifice. This deformation can also prevent complete closure of the valve, which is evidenced by concomitant regurgitation in about half of patients with MS.

Pathophysiology

The cross-sectional area of the normal MV is 4 to 5 cm². Normally, there is a trivial diastolic pressure gradient present to move blood across the MV from the left atrium into the left ventricle. An increasing gradient is required as the MV becomes more narrowed, and a significant transvalvular gradient first develops when there is reduction of the mitral orifice to less than 2.5 cm², which represents mild MS. The increased atrial pressure leads to left atrial enlargement and the pressure is subsequently transmitted retrograde into the pulmonary veins, capillaries, and arteries. The determinants of the transvalvular gradient, and therefore the determinants of the left atrial pressure, are atrial contractility, cardiac output, and heart rate. Consequently, the gradient and atrial pressure are increased if atrial kick is lost (decreased atrial contractility), flow rate across the valve increases (increased cardiac output), or transit time across the valve is shortened (increased heart rate).

Diagnosis

Symptoms. Symptoms of left-sided heart failure, such as dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, are

the primary indicators of MS and are typically triggered by exertion, stress, infection, pregnancy, or the abrupt onset of atrial fibrillation. The increased heart rate and cardiac output that can occur under these circumstances, and the mechanical obstruction inherent to MS, lead to an increased transvalvular gradient and left atrial pressure. The ensuing pulmonary congestion results in dyspnea. Likewise, the loss of atrial kick with atrial fibrillation increases the gradient and atrial pressure. Patients with atrial fibrillation may also present with palpitations or systemic embolization.

Patients infrequently present with hoarseness, dysphagia, hemoptysis, and symptoms of right-heart failure. Hoarseness and dysphagia may result if left atrial enlargement is sufficient to compress surrounding structures. Hemoptysis may occur from significant pulmonary venous hypertension. Symptoms of right-sided heart failure arise when right ventricular function is impaired due to an increased afterload from the stenotic MV and secondary pulmonary hypertension. Still, other patients may present without symptoms but have an abnormal physical examination.

Signs. The left ventricle is typically not enlarged; thus, the point of maximum impulse is not displaced. The typical auscultatory findings of MS are best heard at the apex and include a low-pitched, rumbling mid-diastolic murmur; an accentuated first heart sound; and an opening snap. These findings may be absent with a heavily calcified immobile valve, severe pulmonary hypertension, or low cardiac output. Physical findings of pulmonary hypertension, such as a loud pulmonic component of the second heart sound (P_2), a right ventricular heave, distended neck veins, hepatomegaly, ascites, and peripheral edema, can also be observed with MS.¹⁶

Imaging. Echocardiography is the principal tool used in the diagnosis of MS. It is used to assess the morphologic characteristics of the valve apparatus, which include leaflet mobility, flexibility, and thickness; presence of calcifications and subvalvular fusion; and appearance of the commissures. Additionally, Doppler echocardiography is utilized to determine the hemodynamic severity by measurement of the mean transvalvular pressure gradient, pulmonary artery systolic pressure, and valve area (Table 82.3). This morphology and severity information is fundamental in determining the timing and type of intervention to be used.¹⁷

The enlarged left atrium gives rise to characteristic findings on the chest radiograph, which includes displacement of the left main-stem bronchus superiorly and displacement of the esophagus posteriorly. Additionally, calcification of the mitral leaflets and enlarged pulmonary arteries with cephalization of pulmonary blood flow can be seen.

TABLE 82.3 **DIAGNOSIS**

CLASSIFICATION OF MITRAL STENOSIS SEVERITY

■ INDICATOR	■ MILD	■ MODERATE	■ SEVERE
Mean gradient (mm Hg)	<5	5–10	>10
Pulmonary artery systolic pressure (mm Hg)	<30	30–50	>50
Valve area (cm ²)	>1.5	1.0–1.5	<1.0

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

Similar to the diagnosis of other valvular heart disease, cardiac catheterization with direct pressure measurement has largely been replaced by echocardiography.

Natural History

The natural history of MS is that of a continuous decline usually consisting of a slow, stable course followed by a progressive acceleration. The latent period from rheumatic fever to the onset of symptoms is typically 20 to 40 years, with another decade before symptoms become disabling. Depending on the symptoms at presentation, the overall 10-year survival of untreated patients presenting with MS is 50% to 60%. Once disabling symptoms occur, the 10-year survival is a bleak 0% to 15%.^{22–25} Mortality in untreated patients is due to pulmonary and systemic congestion, systemic embolism, pulmonary embolism, and infection.^{24,26}

Treatment

For the asymptomatic patient with mild MS in sinus rhythm, prophylaxis against rheumatic fever is the only therapy indicated. A yearly history, physical examination, chest radiograph, and electrocardiogram should be obtained; serial echocardiograms are only warranted in patients with severe MS or when there is a change in symptoms.¹⁷

Mechanical relief is considered in symptomatic patients with moderate to severe MS. In symptomatic patients with mild MS, further exercise testing or dobutamine stress testing is useful to determine whether or not mechanical relief is warranted. Patients with a significant elevation of mean transmitral gradient (>15 mm Hg), pulmonary artery systolic pressure (>60 mm Hg), or pulmonary artery wedge pressure (>25 mm Hg) during provocative testing have hemodynamically significant MS and should be considered for mechanical relief.¹⁷ The options for mechanical relief of MS include percutaneous balloon mitral valvotomy, open mitral commissurotomy, and MV replacement.

Percutaneous Balloon Mitral Valvotomy. Percutaneous balloon mitral valvuloplasty (PBMV), where one or more large balloons are inflated across the MV by a catheter-based approach, is the treatment of choice for select patients with MS.¹⁷ Patients with pliable, noncalcified valves and minimal fusion of the subvalvular apparatus are the best candidates for PBMV. Contraindications to this procedure include the presence of a left atrial thrombus, moderate to severe MR, heavy annular or leaflet calcification, and severe subvalvular distortion.

Procedural mortality of PBMV is 1% to 2% in large series. Rare risks of the procedure include MR, iatrogenic creation of an atrial septal defect, perforation of the left ventricle, embolic events, and myocardial infarction.^{27–31} Overall, 80% to 95% of patients have a successful initial outcome with a doubling of the MV area and a 50% to 60% reduction in the transvalvular gradient.

Open Mitral Commissurotomy. Open mitral commissurotomy (OMC) permits direct inspection of the MV apparatus and allows debridement of calcium deposits, division of the commissures, and splitting of fused chordae tendineae under direct vision. Additionally, the left atrial appendage can be surgically oversewn from within the left atrium, reducing the risk of postoperative embolization. The contraindications to OMC are similar to those of PBMV.

The operative mortality of OMC is less than 2%,^{32,33} and complication rates are similar to those of PBMV.^{34,35} Short- and long-term hemodynamic results and symptomatic results are similar between PBMV and OMC in younger patients with less severe valve pathology (lower Wilkins scores).³⁴ More

favorable results are seen with OMC in older patients with subvalvular fusion, leaflet calcification, and less valve flexibility (higher Wilkins scores).³⁵

Mitral Valve Replacement. MV replacement (MVR) is necessary in symptomatic patients with moderate to severe MS when there is a significant amount of calcification or subvalvular fusion, since PBMV and OMC are less likely to be successful. MVR is also necessary in symptomatic patients with moderate to severe MS and concomitant moderate to severe MR.¹⁷ The choice of valve prosthesis for MVR is determined in a similar manner as choosing the prosthesis for AVR. Biologic prostheses are used in the elderly and those in whom long-term warfarin is contraindicated. Regardless of the prosthesis used, it is well established that preservation of the papillary muscle attachments to the annulus plays an important role in the maintenance of LV function.^{36–40}

The operative mortality of MVR is 5% to 6% and freedom from reoperation at 15 years is 50% to 75%.⁴¹

MITRAL REGURGITATION

Prevalence and Etiology

7 Since competency of the MV is dependent on the entire MV apparatus, dysfunction of any one of the components can lead to mitral regurgitation (MR). The most common overall cause of MR is degenerative MV disease. Other causes of MR include rheumatic valve disease, endocarditis, certain drugs, and collagen vascular disease. In some cases, functional MR develops as a result of dilatation of the left ventricle from cardiomyopathy or severe ischemic heart disease. Lastly, rupture of a papillary muscle from myocardial infarction or endocarditis, or rupture of a chord can lead to the onset of acute, severe MR.

Pathophysiology

MR is caused by deficient coaptation of the MV leaflets, which results in blood flow from the left ventricle into the left atrium during systole. Regardless of etiology, the pathophysiology of chronic MR is similar. MR results in gradual enlargement of the left atrium as a result of volume overload. Decrease in the functional stroke volume causes an increase in LV size with a subsequent decrease in LV function.

On the other hand, the pathologic process that takes place in acute MR is quite different. Sudden volume overload results in an increase in LV preload and a decrease in forward stroke volume, since compensatory LV eccentric hypertrophy has not

had time to develop. Similarly, acute volume overload of the left atrium results in an increase in left atrial pressure and pulmonary congestion.

Diagnosis

Symptoms. Symptoms of chronic MR include fatigue, dyspnea on exertion, and shortness of breath. More advanced stages of disease are characterized by the development of heart failure. Acute, severe MR is characterized by acute pulmonary edema and cardiogenic shock.

Signs. The point of maximum impulse is typically laterally displaced. The classic auscultatory findings of MR are best heard at the apex and include a high-pitched, blowing, holosystolic murmur radiating to the axilla; a diminished S₁; and an S₃.

Imaging. Echocardiography is used to assess the severity of MR, morphology of the MV, and size and function of the left ventricular and atrium. Assessment of the severity of MR is determined by the jet area/left atrial area, regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 82.4). Additionally, magnetic resonance imaging allows accurate measurements of the severity of regurgitation and quantification of regurgitant volumes, along with assessment of LV size and function.

Natural History

Patients with mild to moderate MR usually remain asymptomatic with little or no hemodynamic compromise for many years. In patients with severe MR caused by flail leaflets, mortality is 6% to 7% per year, and 90% of patients die or require an MV operation within 10 years.⁴²

Treatment

Medical therapy is indicated in asymptomatic patients with mild to moderate chronic MR and preserved LV function.

Surgery is indicated in symptomatic patients with severe MR as well as in asymptomatic patients with severe MR and LV dysfunction. MV repair is the preferred surgical therapy for most patients with MR, since it preserves the native valve and avoids the need for anticoagulation, which is required in the majority of patients who undergo valve replacement.⁴³ Preservation of the MV and chordae preserves LV function and improves survival. Success rates of MV repair depend on the etiology of regurgitation. Durable MV repair can be accomplished

TABLE 82.4

DIAGNOSIS

CLASSIFICATION OF MITRAL REGURGITATION SEVERITY

■ INDICATOR	■ MILD	■ MODERATE	■ SEVERE
Angiographic grade	1+	2+	3–4+
Jet size			Wall-impinging jet of any size
Jet area/left atrial area (%)	<20	20–40	>40
Regurgitant volume (mL/beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm ²)	<0.20	0.20–0.39	≥0.40

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

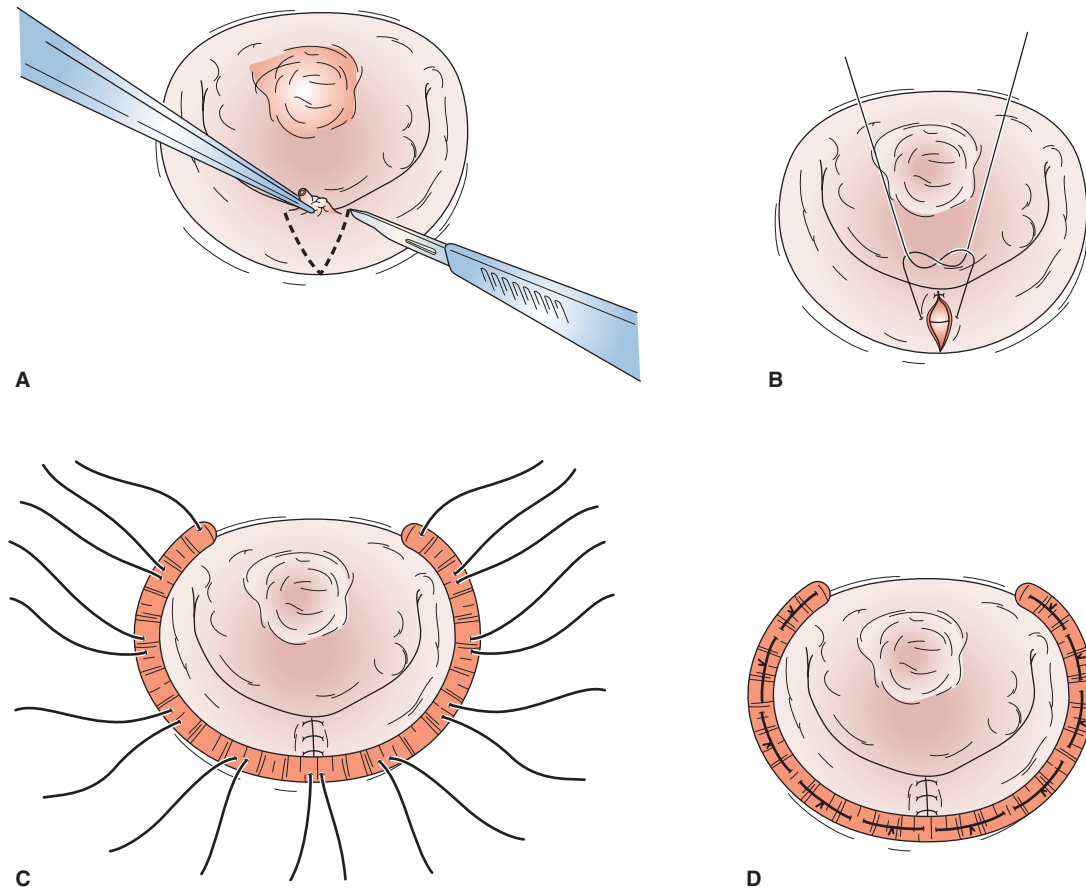

FIGURE 82.8. Schematic diagram of posterior mitral valve repair and insertion of annuloplasty ring.

in more than 90% of patients with degenerative MV disease. Standard techniques for MV repair include resection of the prolapsed portion of the MV leaflet, leaflet reconstruction, and insertion of an annuloplasty ring (Fig. 82.8).

Mortality of isolated MV repair is less than 1%, with greater than 90% freedom from reoperation at 10 years. Functional MR is usually repaired with the use of an undersized

annuloplasty ring to reduce the diameter of the mitral annulus and restore valve competency. MV repair is also the preferred surgical therapy in patients with MV endocarditis. Resection of all infected valve tissue is the mainstay of valvular reconstruction in patients with endocarditis. This is followed by leaflet reconstruction, commonly with the use of an autologous pericardial patch and an annuloplasty (Fig. 82.9).

FIGURE 82.9. Schematic diagram of mitral valve repair with autologous pericardial patch and insertion of an annuloplasty ring.

FIGURE 82.10. Surgical approaches to the mitral valve. A: Full sternotomy. B: Partial sternotomy. C: Limited right anterolateral mini-thoracotomy. D: Robotically assisted.

MVR is indicated for patients in whom adequate MV repair cannot be accomplished. Mechanical valve replacements are indicated in patients younger than 65 years of age and stented bioprostheses are indicated in the elderly.

Isolated MV repair and replacement are most commonly performed through a full sternotomy. Minimally invasive approaches, which include the partial upper and lower sternotomy and limited right thoracotomy, decrease the degree of surgical trauma and blood loss and allow faster recovery. Robotically assisted MV repair, which is performed through small port-like incisions, is the least invasive surgical approach and eliminates the need for sternotomy or thoracotomy (Fig. 82.10).⁴⁴

TRICUSPID VALVE DISEASE

Tricuspid valve (TV) disease is less common than AV and MV disease. Tricuspid regurgitation (TR), the most common form of TV dysfunction, can occur with anatomically normal or abnormal valves. Functional TR is caused by right ventricular dilatation and consequent leaflet malcoaptation in an otherwise anatomically normal valve. Right ventricular enlargement occurs in patients with pulmonary hypertension, most commonly caused by longstanding MV dysfunction. TV endocarditis most commonly occurs in intravenous drug users and causes TR by destruction of the leaflets.

Echocardiography is used to assess the degree of TR, anatomy of the TV, right ventricular function, and pulmonary pressures.

Mild to moderate degrees of TR often resolve spontaneously once the MV disease causing the pulmonary hypertension is corrected. Severe functional TR is corrected by reduction in the diameter of the tricuspid annulus, most commonly using an annuloplasty ring. Severe endocarditis requires complete resection of infected valve tissue, followed by TV replacement with a bioprosthesis. In active drug users, insertion of a valve prosthesis may be delayed by several months to decrease the risk of recurrent endocarditis.

VALVE PROSTHESES

Development of valve prostheses has transformed the treatment of valvular heart disease. Numerous types of prostheses are currently available for clinical use, and they differ in design, biocompatibility, and hemodynamic characteristics. They are broadly classified into mechanical and bioprosthetic.

Contemporary mechanical valves are bileaflet valves composed of carbon material that is mounted on a sewing ring (Fig. 82.5). Mechanical valve prostheses are durable and have excellent hemodynamic performance. Patients with mechanical prostheses require lifelong anticoagulation with warfarin, which results in a 1% to 3% risk of bleeding per year. These characteristics make mechanical valves the prosthesis of choice for younger patients with no contraindications to long-term anticoagulation.¹⁷

Biologic prostheses are composed of valve leaflets created from bovine pericardium or porcine valve leaflets mounted on a sewing ring (Fig. 82.6). Biologic prostheses have slightly

inferior hemodynamic characteristics when compared with mechanical prostheses and a limited durability of 10 to 15 years. However, bioprostheses are not thrombogenic and therefore do not require anticoagulation. Bioprostheses are generally indicated in older individuals and younger patients who have contraindications to long-term anticoagulation. There has been an increased use of bioprostheses in younger individuals due to recent improvements in design of the prostheses, expected increases in valve durability, and decreased risk of reoperations.

Aortic homografts are cryopreserved allografts that are composed of AVs and ascending aortas. Homografts are not thrombogenic, have excellent hemodynamic characteristics, and have high resistance to infection. Homografts are indicated in patients with AV endocarditis. Their use for primary AVR is limited due to the complexity of the operation and limited durability (10 years).

CARDIAC TUMORS

Cardiac tumors can be located in the epicardium, myocardium, endocardium, or any combination of the three. In general, tumors that involve the parietal pericardium are not classified as cardiac tumors.

Tumors of the heart are classified as either primary or secondary. Primary tumors arise in the heart and are either benign or malignant. Secondary tumors are metastases from primary tumors arising elsewhere and hence are always malignant. Primary tumors are rare, with an autopsy incidence of less than 0.1%.⁴⁵ Secondary tumors are observed more commonly, with a postmortem incidence of about 1%.⁴⁶

Cardiac tumors present with variable symptoms. Symptoms are frequently determined by the intracardiac location of the tumor. Intracavitary tumors can obstruct blood flow, caus-

ing signs and symptoms that mimic those of valvular heart disease. Intracavitary tumors can also cause embolic events, resulting in symptoms related to the site of embolization. Intramyocardial tumors can trigger cardiac rhythm disturbances, including sudden death.⁴⁷ Cardiac tumors can also cause systemic symptoms mimicking collagen vascular disease, malignancy, or infective endocarditis.⁴⁷

BENIGN PRIMARY CARDIAC TUMORS

Myxomas

Definition, Incidence, and Prevalence. Myxomas are the most common primary cardiac tumors. They are benign. Although myxomas have been reported in both genders and in all age groups, they most often occur in women in the third to sixth decades of life. Myxomas are usually sporadic, but at least 7% occur as part of an autosomal dominant syndrome.

Morphology. Arising from the endocardium, myxomas usually extend into a cardiac chamber. They are generally polypoid, pedunculated lesions with a smooth surface that may be covered with thrombus (Fig. 82.11A). The tumors range in size from 1 to 15 cm, but are most commonly about 5 cm.^{48–51} Myxomas are thought to arise from pluripotent mesenchymal cells. Histologically, myxomas consist of a matrix of acid mucopolysaccharide (Fig. 82.11B).⁴⁵ Myxomas most commonly occur in the atria. Approximately 75% arise in the left atrium, and 15% to 20% arise in the right atrium.⁵⁰ The remainder of myxomas are located in the ventricles.

Clinical Characteristics. Many patients with myxomas are asymptomatic. The myxoma may be detected by routine

FIGURE 82.11. Left atrial myxoma. **A:** Gross photograph showing large pedunculated lesion arising from the left atrium and extending into the mitral valve orifice. **B:** Microscopic appearance, with abundant acid mucopolysaccharide, scattered collections of myxoma cells, and abnormal vascular formations (arrow). (Reproduced with permission from Kumar V, Abbas AK, Fausto N. *Robbins and Cotran Pathologic Basis of Disease*, 7th ed. Philadelphia: Elsevier; 2005.)

screening echocardiography performed for other indications. Asymptomatic myxomas should be excised in order to prevent emboli, valvular dysfunction, or constitutional symptoms.

Patients with myxomas can have a variety of symptoms. In the sporadic form, classic findings include emboli, congestive heart failure caused by obstruction of cardiac blood flow, and constitutional symptoms. These sequelae are related to the location, size, and mobility of the tumor. Because most myxomas arise in the left atrium, systemic embolization is common, occurring in 30% to 50% of cases.^{52–54}

Myxomas also can display signs and symptoms related to cardiac obstruction. Typically, the findings are related to the tumor's ability to impede filling of the ventricles; in such instances, signs and symptoms may mimic those of mitral or tricuspid valve stenosis. Constitutional symptoms include fever, malaise, rash, weight loss, and myalgia.

Diagnosis. Echocardiography is the imaging modality of choice for diagnosis of myxomas. In cases of diagnostic uncertainty, magnetic resonance imaging (MRI) and computed tomography (CT) may be helpful. Final diagnosis is confirmed by pathologic examination.

Management. Surgical resection is the mainstay of treatment. Great care must be taken to minimize manipulation of the heart before cross-clamping the aorta to reduce the risk of intraoperative tumor embolization. A variety of approaches are available for resection of left atrial tumors. In the absence of other cardiac disease, a minimally invasive or robotically assisted operation can be employed to speed postoperative recovery. The tumor is resected en bloc. Tumors that arise from a relatively well-defined pedicle can be excised without full-thickness excision of a button of atrial wall. The results of surgical excision are good with a low risk of morbidity and mortality (0% to 3%).^{55–57}

Other Benign Primary Tumors

Rhabdomyoma. Rhabdomyoma is the most common cardiac tumor in children and the second most common benign cardiac tumor overall.⁵⁰ Most occur in children younger than 1 year of age. Rhabdomyoma is a benign tumor composed of cardiac myocytes. About one half of patients with rhabdomyoma have tuberous sclerosis, and about one half of patients with tuberous sclerosis develop rhabdomyomas.⁵⁸ These tumors occur sporadically or in conjunction with other rare congenital heart malformations.

Rhabdomyomas usually are found deep in the myocardium; they may extend into the cardiac chambers. They are of variable size, ranging from 1 mm to several centimeters. Most rhabdomyomas are multicentric and involve both ventricles. Because of their morphologic appearance and multicentric nature, rhabdomyomas are classified as hamartomas rather than as true tumors.⁵⁹ Pathologically, they are distinguishable from the surrounding myocardium by their firm, gray, nodular characteristics.⁶⁰

Most children with rhabdomyomas display cardiac arrhythmias or obstructive symptoms in the first few days or weeks of life. Rhabdomyomas causing significant intracardiac obstruction to blood flow can result in death within 24 hours of birth; patients with less severe disease may be asymptomatic for years. The diagnosis is usually made by echocardiography. One of the curiosities of this tumor is the well-documented tendency for these tumors to regress.^{61,62}

In most cases these tumors are not resected. Surgical resection is reserved for masses that cause significant cardiac obstruction.^{63,64} Given the multicentricity of the lesions and their limited growth potential, the operative approach is conservative debulking, with the goal being relief of outflow obstruction with preservation of electrical conduction and myocardial and valvular function.

Lipomas. Lipomas are encapsulated masses of adipose tissue that usually arise from the myocardium or pericardium.⁵⁰ They are usually small but can grow to be massive. Lipomas involving the pericardium may be mistaken for pericardial cysts and may be associated with pericardial effusions. Although most of these tumors are identified after death, they can be diagnosed by echocardiography and MRI. Most cardiac lipomas can be observed. However, lipomas causing obstructive symptoms or arrhythmias should be resected.

Papillary Fibroelastoma. Papillary fibroelastomas are the most common tumors affecting cardiac valves.^{65,66} They usually involve the valves of the left side of the heart, and typically occur in adult patients.⁶⁷ Although papillary fibroelastomas usually are asymptomatic, when symptoms occur, they are most frequently related to embolization. The tumors are identified by echocardiography. Surgical excision is advised, even in asymptomatic patients.^{65,68,69} When resection is performed, a minimally invasive surgical approach is generally possible.

MALIGNANT PRIMARY CARDIAC TUMORS

Angiosarcoma

Most malignant cardiac tumors are metastases from other malignancies.⁵¹ Almost all primary malignant tumors of the heart are sarcomas⁷⁰; angiosarcoma is the most common malignant primary cardiac tumor.⁵⁰ Angiosarcomas are usually solitary, large bulky masses that originate in the right atrium (Fig. 82.12). They may extend into the right atrial cavity, causing valvular obstruction, right-sided heart failure, or

FIGURE 82.12. Gross photograph of angiosarcoma of the right ventricle. (Reproduced with permission from Kumar V, Abbas AK, Fausto N. *Robbins and Cotran Pathologic Basis of Disease*, 7th ed. Philadelphia: Elsevier; 2005.)

hemorrhagic pericardial effusion with tamponade.⁷⁰ Most of these tumors metastasize, most commonly to the lung, liver, or brain.⁷¹ Angiosarcomas are very aggressive, and survival after diagnosis ranges from 3 to 15 months.⁵⁹ Given their rapid growth and poor prognosis, surgical resection is rarely successful.

Rhabdomyosarcoma

Rhabdomyosarcoma is the second most common cardiac sarcoma. Like angiosarcoma, it is more common in men.^{72–74} Unlike angiosarcoma, rhabdomyosarcoma does not have a predilection for a particular cardiac chamber.⁵⁰ It may occur at multiple sites and extend into the pericardium. Patients may have cardiac obstructive or constitutional symptoms. Prognosis is poor, and surgical resection is usually ineffective.

SECONDARY CARDIAC TUMORS: METASTASES TO THE HEART

Metastatic tumors to the heart, or secondary tumors, are much more common than are primary cardiac tumors. Secondary tumors are usually carcinomas rather than sarcomas because of the relative frequency of these cancers.⁷⁰ Hematogenous spread is the most common mode of metastasis, but lymphatic spread and direct extension also occur.

Symptoms occur most commonly in patients with pericardial metastases rather than intramural or intracavitary involvement. The symptoms associated with metastases are congestive heart failure and arrhythmias. Metastases to the heart should be suspected in patients with known neoplasms who develop congestive heart failure.

Carcinoma of the lung and breast may directly invade the parietal and visceral pericardium, causing myocardial restriction and pericardial effusion.⁷⁰ Melanoma commonly metastasizes to the myocardium, as do leukemia and lymphoma. The treatment of metastatic tumors depends on the tumor type and symptoms. Given the late stage at which cardiac metastases occur and the poor prognosis, few of these patients are candidates for cardiac surgical intervention. Lymphoma and leukemia may respond to chemotherapy or radiotherapy. Symptomatic malignant pericardial effusions may be drained by creation of a pericardial window, temporarily relieving symptoms.

CHAPTER 83 ■ ISCHEMIC HEART DISEASE

JONATHAN W. HAFT

KEY POINTS

- 1 Because of its unique physiology, the heart is particularly susceptible to ischemic injury.
- 2 Atherosclerotic plaques cause ischemia from chronic flow limitations or from unstable plaque rupture.
- 3 Patients with coronary artery disease will present with either chronic stable angina or an acute coronary syndrome, which consists of unstable angina, a non-ST-segment myocardial infarction, or an ST-segment myocardial infarction.
- 4 Several well-described complications from myocardial infarctions must be anticipated and recognized early.
- 5 Medical treatment of coronary artery disease includes lifestyle modifications and medications to slow the progression and stabilize atherosclerotic plaques.
- 6 Percutaneous intervention (PCI) of coronary lesions has improved dramatically in recent years to include drug-eluting intracoronary stents.
- 7 Coronary artery bypass grafting (CABG) involves creation of alternative conduits from the systemic circulation to the epicardial coronary arteries.
- 8 The left internal mammary artery is the superior conduit for CABG.
- 9 CABG remains superior to both medical treatment and PCI for patients with left main or three-vessel disease or for patients with two-vessel disease involving the left anterior descending artery associated with left ventricular dysfunction.

CORONARY ANATOMY AND PHYSIOLOGY

The right and left coronary arteries originate from the aorta just above the aortic valve cusps (Fig. 83.1). The orifices of the two arteries within the sinuses of Valsalva designate the

right and left coronary cusps. The third aortic valve cusp is referred to as the noncoronary cusp. The coronary circulation is traditionally divided into three major territories: the left anterior descending (LAD) and the circumflex territories originate from the left coronary artery, and the right coronary territory usually comes from the right coronary artery.

FIGURE 83.1. Anatomy of the cardiac circulation. A: Anterior view. B: Posterior view.

The origin of the left coronary artery is referred to as the left main and travels posterolaterally to the left behind the pulmonary artery, where it divides into two main branches, the LAD and the circumflex coronary artery. The length of the left main coronary artery is variable, but rarely exceeds 2 cm. Unusually, the left main is absent, where the circumflex and LAD originate from the aorta via two separate ostia.

The LAD coronary artery emerges from behind the pulmonary artery and travels inferiorly within the interventricular groove to the cardiac apex, sometimes wrapping around it onto the posterior interventricular groove. The LAD gives off two different types of branches: diagonals and septals, both of which are highly variable in size and number. The diagonals take off at acute angles and perfuse the anterolateral surface of the left ventricle. Septal branches, the first of which is typically quite prominent, emerge at a right angle from the LAD and supply the interventricular septum. The LAD is the most prominent of the three coronary territories described, and carries approximately 50% of left ventricular myocardial blood flow, supplying the anterior, anterolateral, septal, and apical walls.

The circumflex coronary artery continues from the left main coronary and travels within the posterior atrioventricular groove. Branches from the circumflex are called obtuse marginal arteries, and also vary greatly in size and number. In 80%

to 90% of people, the terminal branch of the circumflex supplies the posterolateral wall of the left ventricle. In the remaining 10% to 20%, the circumflex continues to the posterior interventricular septum and terminates as the posterior descending artery (PDA). This is referred to as a left dominant heart, where the left main coronary artery is supplying the posterior interventricular septum. Some patients will have a third branch of the left main referred to as the ramus intermedius, or intermediate branch. If present, this vessel is typically large, and supplies much of the anterolateral wall of the left ventricle.

The right coronary artery originates from the anterior right sinus of Valsalva and descends in the right atrioventricular groove. One or more acute marginal branches feed the right ventricular free wall. In 80% to 90% of patients, the right coronary artery continues to the posterior interventricular septum and supplies the PDA and often a variable-sized right posterolateral artery. This is referred to as a right dominant heart. Near the origin of the posterior descending branch, a small characteristic vessel can be seen supplying the atrioventricular node. This branch can become important in acute right coronary artery occlusions, resulting in life-threatening heart block and bradycardia. A small proximal branch of the right coronary artery supplies the sinus node on the anterolateral surface of the superior vena cava.

Anomalous origin of the coronary arteries is common, occurring in 0.3% to 1% of the population, and their anatomy is varied and complex. Rarely, the left coronary arises from the pulmonary artery. This pathology is diagnosed in infancy, as the myocardium becomes profoundly ischemic when pulmonary vascular resistance falls and myocardial perfusion decreases. If left uncorrected, it is universally fatal. The coronaries may also originate from atypical aortic root sinuses, and their trajectory is variable. The most worrisome problem occurs when the left anterior descending or left main coronary artery originates from the right sinus of Valsalva. When the LAD travels posteriorly and to the left, it courses between the pulmonary artery and the aortic root. This trajectory is described as “malignant” because of the potential for compression between the great vessels, particularly during accentuated wall stress, such as with exercise. Although there is little evidence, it is generally accepted that a revascularization strategy should be considered in symptomatic patients with “malignant” coronary anomalies or in asymptomatic patients with demonstrable ischemia on noninvasive testing.¹

Venous anatomy is more predictable, and very little pathology within this system is encountered. Three named venous branches can be identified: the middle cardiac vein in the posterior interventricular groove, the posterior cardiac vein along the obtuse margin of the heart, and the great (or anterior) cardiac vein along the anterior interventricular groove. All three drain into one confluence known as the coronary sinus along the posterior atrioventricular groove (Fig. 83.1). The coronary sinus empties posteriorly into the right atrium between the inferior vena cava and the annulus of the tricuspid valve. In addition to these identifiable named veins, the myocardium also drains directly into all chambers of the heart via thebesian veins.

1 Myocardial work consumes an enormous amount of energy substrate. In fact, only 10% to 20% of myocardial energy requirements are related to basal functions; the remainder is utilized during the continuous energy-dependent calcium mobilization and myofilament cross-linking from cyclic contraction and relaxation. Even at rest, the heart maximally extracts oxygen delivered from the bloodstream, leaving venous saturation in the coronary sinus typically 20% or less. Thus, increased energy requirements must be met with augmentation in blood oxygen delivery. Contrarily, other less oxygen-dependent tissues, where venous saturation can be as high as 80%, can extract additional oxygen during stress. When insufficient supply of oxygen is available, as may be the case with extreme consumption or limited blood flow, anaerobic metabolism cannot generate enough energy substrate to perform myocardial contraction.² As a result, cardiac function deteriorates immediately and can be observed clinically essentially within heartbeats. Increases in cardiac oxygen consumption must be met with proportional increases in myocardial blood flow.

The heart and its coronary circulation have a unique capacity to dramatically increase blood flow, and thus oxygen delivery, during periods of increased needs.³ While basal coronary blood flow is approximately 10 mL/kg, this value can increase up to sixfold with exercise by autoregulatory mechanisms and feedback loops. Specifically, adenosine accumulates from the breakdown of the energy substrate adenosine triphosphate (ATP). Vasodilatory receptors within the media of coronary arteries are particularly avid for adenosine, increasing blood flow to myocardial regions with increased energy consumption. In addition, increased myocardial activity activates nitric oxide synthase within coronary endothelial cells, producing the powerful vasodilator nitric oxide. By immediately altering the vessel diameter and thus changing the resistance properties of epicardial vessels, these two short-acting mediators can rapidly alter coronary flow rates to meet changing energy requirements.

In addition to the high metabolic requirements of the heart and its dependence on responsive changes in blood flow, the coronary circulation is further uniquely challenged. During systole, increased cavitory pressure compresses intramyocardial

vessels and virtually eliminates forward flow. As a result, blood flow to the left ventricle occurs only during diastole, so that myocardial perfusion depends not only on coronary arterial patency and caliber, but also on the diastolic pressure gradient and the duration of diastole. Tachycardia not only increases oxygen consumption, but also reduces the time available for myocardial perfusion, increasing the demands for epicardial flow. The rise in ventricular diastolic pressure seen in heart failure also reduces perfusion pressure and can jeopardize ischemia in vulnerable territories. With an understanding of cardiac perfusion needs and mechanics, it is apparent why occlusive lesions in coronary arteries can restrict blood flow, producing ischemia and infarction.

CORONARY ATHEROSCLEROSIS

Atherosclerosis is a progressive multifocal disease of medium and large muscular arteries of the systemic circulation. Atherosclerotic plaques or atheromas can occur anywhere in the systemic circulation, but tend to present clinically in varying quantities in the coronary circulation, carotid arteries, splanchnic vessels, and lower extremities. The lesions tend to occur predominantly at vessel bifurcations, sharp curvatures, and other regions creating pressure wave reflections and recirculation.⁴ All plaques consist of smooth muscle proliferation and intracellular and extracellular lipid deposition within the arterial intima (Fig. 83.2). The predecessor “fatty streaks” seen in the first two decades of life are small and unobstructing. However, under certain clinical circumstances, endothelial injury from cigarette smoke, hypercholesterolemia, hyperglycemia, hypertension, or other causes of inflammation initiates a cascade of events. These include endothelial dysfunction with expression of adhesion molecules, which bind circulating inflammatory cells like monocytes. The activated monocyte transmigrates into the vessel wall and ingests accumulated lipids. In turn, they release cytokines, which enhance endothelial cell adhesion molecule expression; alter endothelial cell nitric oxide production, promoting vasoconstriction and platelet activation; and stimulate activation of other inflammatory cells including neutrophils and T lymphocytes. The activated monocytes accelerate further lipid accumulation and smooth muscle cell proliferation. The end result is an enlarging plaque encroaching on the arterial lumen, separated from the bloodstream by a collagen-rich fibrous plaque.

2 Within the coronary circulation, atherosclerotic stenotic lesions are generally restricted to the proximal regions of the large epicardial coronary arteries. In particular, stenosis found in the LAD and circumflex vessels are frequently isolated, short, and in the proximal segments. The right coronary artery, however, develops diffuse obstructions, although rarely extending into the posterior descending or intramural branches. For reasons that are unclear, atherosclerosis is rarely found within intramyocardial segments of the coronary arteries. Symptoms from these atherosclerotic plaques can occur from a variety of proposed mechanisms. First, the lesion can cause flow limitations, particularly when the luminal cross-sectional area is reduced by at least 75%. With this degree of obstruction, the vasodilatory reserve required during increased myocardial demand is restricted, resulting in transient myocardial ischemia until demand returns to baseline, also known as exertional angina. The atherosclerotic plaque also causes coronary ischemia when the lesion becomes unstable. The fibrous plaque can fracture or rupture, exposing the bloodstream to the highly thrombogenic internal plaque contents. This can lead to complete epicardial thrombosis, the presumed mechanism of ST-segment elevation myocardial infarction (STEMI). Additionally, subtotal plaque disruption can cause vasoconstriction, platelet activation, and embolization, resulting in ischemia without total occlusion of the epicardial vessel. This is the presumed mechanism of

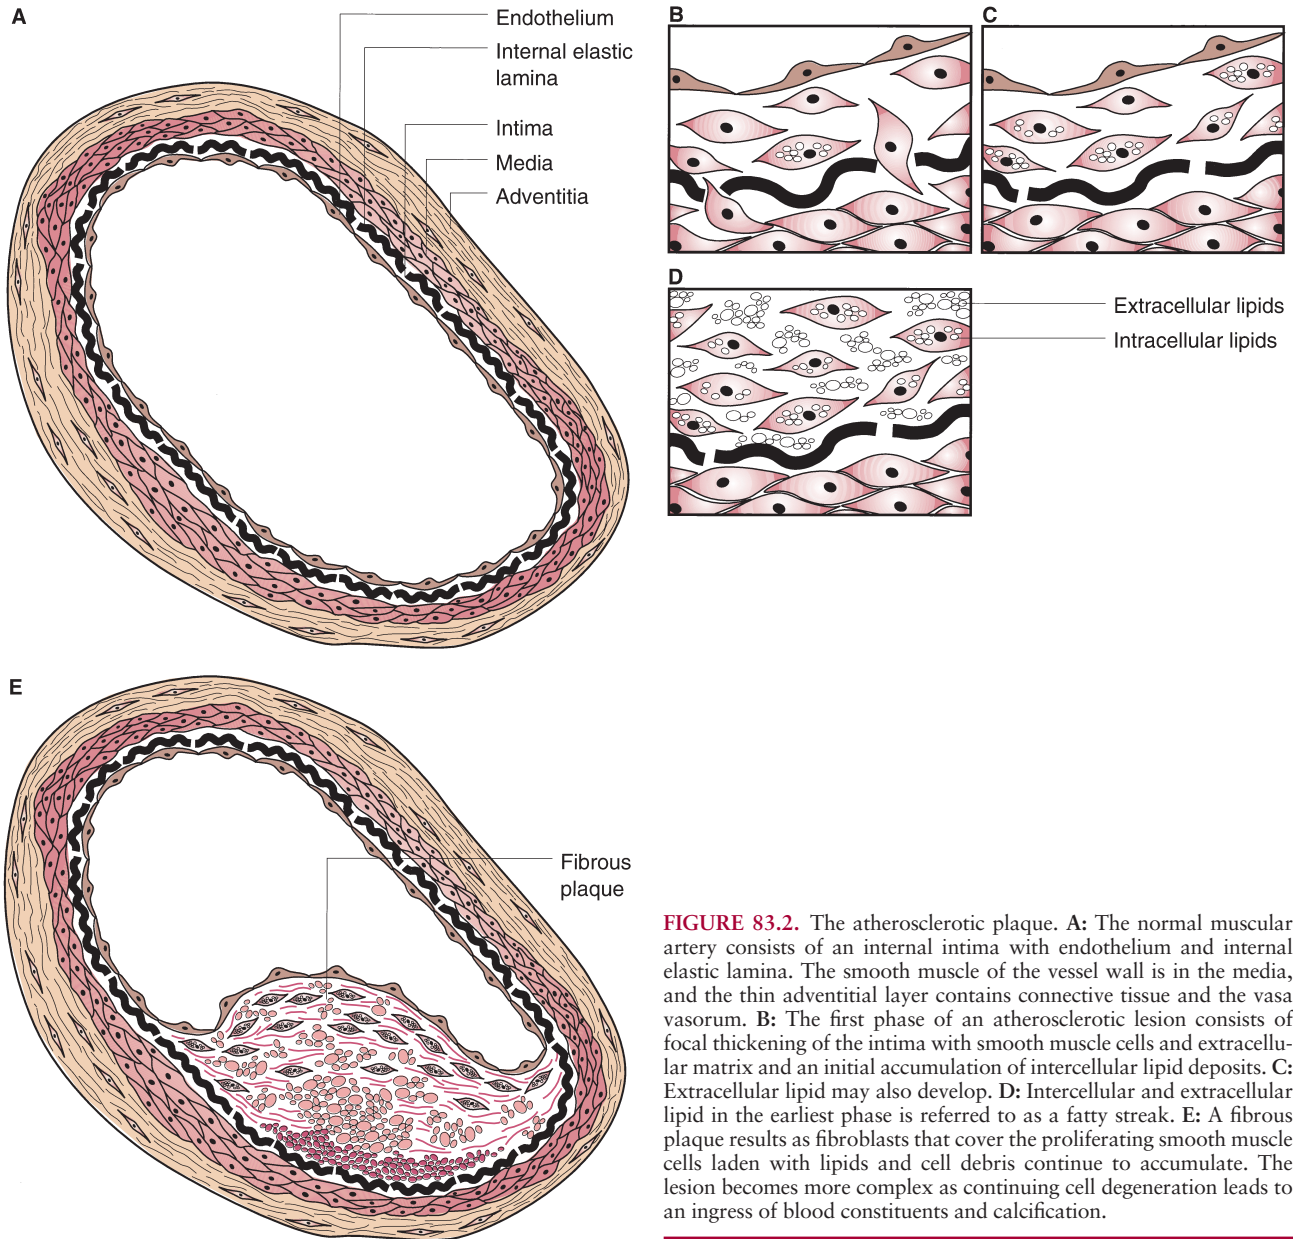

FIGURE 83.2. The atherosclerotic plaque. **A:** The normal muscular artery consists of an internal intima with endothelium and internal elastic lamina. The smooth muscle of the vessel wall is in the media, and the thin adventitial layer contains connective tissue and the vasa vasorum. **B:** The first phase of an atherosclerotic lesion consists of focal thickening of the intima with smooth muscle cells and extracellular matrix and an initial accumulation of intercellular lipid deposits. **C:** Extracellular lipid may also develop. **D:** Intercellular and extracellular lipid in the earliest phase is referred to as a fatty streak. **E:** A fibrous plaque results as fibroblasts that cover the proliferating smooth muscle cells laden with lipids and cell debris continue to accumulate. The lesion becomes more complex as continuing cell degeneration leads to an ingress of blood constituents and calcification.

unstable angina and non-ST-segment elevation myocardial infarction (NSTEMI). Some plaques are more prone to rupture than others, and the composition of the fibrous cap may be an identifiable feature of an unstable lesion. Activation of inflammatory cells may increase the activity of matrix metalloproteinases, which degrade components of the fibrous cap. Some theorize that certain stressors can stimulate activation of these inflammatory cells, such as acute infections, extreme cold, and even emotional distress.⁵ The inflammatory component of coronary artery disease has been demonstrated by the strong relationship between C-reactive protein and the incidence of acute myocardial infarctions.⁶

Although the characteristics, locations, and severity of lesions in each person can vary, a number of established risk factors appear to predispose to atherosclerosis. These include advanced age, family history, male sex, hypertension, diabetes mellitus, dyslipidemia, and cigarette smoking. Recognizing the presence of these risk factors can help identify patients at risk of coronary atherosclerosis. In addition, some of these risk factors are modifiable, and simple interventions can reduce their risk of future cardiac events.

Hypertension is strongly associated with the development of atherosclerotic heart disease and the risk of death from cardiovascular causes. Although the mechanism is uncertain, it has been suggested that an increase in shear stress at particular vessel locations may injure the vascular endothelium, predisposing to lipid deposition and plaque development. Systolic hypertension appears to be more predictive than diastolic hypertension, particularly in elderly patients. Numerous interventions can control hypertension, but the most effective appears to be lifestyle modifications including reduction in dietary sodium, exercise, and weight loss. Several classes of medications are used for blood pressure control, and each is variably efficacious in different populations of patients.⁷ Unequivocally, reduction in elevated systolic blood pressure reduces the risk of death from cardiovascular disease, and in particular of atherosclerotic coronary artery disease.

Patients with diabetes are two to four times more likely to have coronary artery disease, and even more so when they are insulin dependent and in diabetic women. In addition, patients with diabetes and coronary disease have worse outcomes than age-matched nondiabetics. Unfortunately, rigorous control of

elevated blood glucose concentrations by insulin does not appear to affect coronary mortality as well as control of other risk factors such as hypertension, dyslipidemia, and smoking cessation does.⁸

Dyslipidemia is associated with accelerated coronary artery disease. This includes both elevation of total cholesterol levels and an imbalance in the ratio of the subcomponents of cholesterol: high-density lipoprotein (HDL) and low-density lipoprotein (LDL).⁹ HDL levels appear to be protective, as the total HDL level is inversely proportional to the risk for the development of coronary artery disease. Conversely, LDL levels are directly proportional to cardiovascular risk. Importantly, alteration in total cholesterol and the ratio of HDL to LDL by dietary changes, medications, and exercise can reduce the risk of cardiovascular events.¹⁰

Cigarette smoking is one of the most important risk factors for coronary artery disease. Carbon monoxide and nicotine directly adversely affect endothelial cell function. In addition, cigarette smoke can increase LDL levels, reduce HDL levels, increase fibrinogen levels, and increase platelet aggregation. Regular smokers have a four to five times higher rate of cardiovascular death than nonsmokers, and there appears to be a dose relationship, with heavier smokers having a higher prevalence of coronary disease than lighter smokers. Fortunately, the risk of developing coronary artery disease is reduced by 50% after 1 year of smoking abstinence, and at 10 years the risk is no different from that of those who never smoked.¹¹

PATIENT PRESENTATION

The clinical manifestations of ischemic heart disease result from an imbalance of myocardial oxygen supply and consumption. The symptoms and acuity depend on the severity and nature of the patient's occlusive lesions, but also on his or her other medical comorbidities. As many as 25% of patients diagnosed with coronary artery disease have no clear symptoms. The diagnosis is often made based on abnormalities identified on screening tests obtained because of the presence of worrisome risk factors.

3 Chronic stable angina is the most frequent complaint of the patient with coronary artery disease. At rest, coronary blood flow is adequate to meet myocardial demand, and patients are without symptoms. However, during exercise or stress, as myocardial oxygen demand increases, the autoregulatory mechanisms to vasodilate and increase myocardial blood flow are constrained. Significant coronary obstructing atheromas become flow limiting, resulting in an imbalance of oxygen demand and supply. Chest pain develops rapidly and builds up quickly, typically described as tightness, squeezing, constricting, or aching. It is usually midsternal and radiates to the left shoulder, arm, jaw, or neck. The classically described Levine sign with a clenched fist over the sternum is a common finding. Some patients, however, will describe symptoms that are collectively referred to as "anginal equivalents." These include dyspnea, diaphoresis, nausea, abdominal pain, heartburn, and dizziness or presyncope. Although the differential diagnoses of these "atypical" symptoms are broad, they should prompt the clinician to think of coronary disease, particularly if risk factors predominate. Interestingly, women are more likely to describe atypical symptoms, resulting in late or missed diagnosis of coronary atherosclerosis. Although the clinical manifestations of angina are variable, the pathognomonic feature of chronic stable angina is that the symptoms occur predictably with exertion and are always relieved with rest. Symptoms of patients with coronary atherosclerosis can be categorized according to the Canadian Heart Association Classification scheme. Class I patients have no symptoms, class II patients have angina with significant exertion, class III patients describe angina with mild exertion, and class IV patients have angina at rest.

Acute coronary syndromes (ACSs) refer to a spectrum of accelerated coronary occlusive disease states and include unstable angina, NSTEMI, and STEMI. Approximately 1 million people are hospitalized in the United States each year with a diagnosis of ACS. Unstable angina refers to patients with chest pain or an anginal equivalent that is new in onset, occurs at rest, or occurs with increasing severity and frequency from their baseline chronic stable symptoms, also referred to as crescendo angina. Patients who develop an NSTEMI have evidence of myocardial injury with elevated blood levels of myocardial enzymes (troponin and the MB fraction of creatine kinase). Unstable angina and NSTEMI are important prognostic indicators, as 10% of patients will die of cardiovascular causes within 6 months.

STEMI represents the consequences of large epicardial vessel occlusion, typically associated with plaque rupture. Patients describe a severe retrosternal pain that persists for at least 30 minutes, but usually for several hours. The pain is frequently characterized as crushing, squeezing, or boring, and can radiate down the left arm or into the jaw. Patients with previous chronic stable angina will report that the current pain is similar to but more intense than their baseline symptoms and has not resolved with rest or nitroglycerine. However, many patients that present with an STEMI never had chronic stable angina. Patients will often describe additional symptoms such as diaphoresis, nausea, dizziness, and epigastric pain. In emergency departments, the pain is often mistaken for gastroenteritis or indigestion, particularly in women. Often in elderly patients and those with diabetes, chest pain may not be present at all, and the only symptom associated with STEMI is heart failure from progressive loss of myocardial contractile function. Although improvements in health systems have drastically increased survival from myocardial infarction, mortality for STEMI remains near 10%.

COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTIONS

4 STEMI can create widespread myocyte necrosis, often resulting in catastrophic complications that require urgent intervention. Anticipation and early diagnosis can improve outcomes. These complications include cardiogenic shock, postinfarct ventricular septal defect, free wall rupture, and acute mitral valve regurgitation (Table 83.1).

Cardiogenic Shock

Cardiogenic shock is a state in which cardiac output is insufficient to meet metabolic demands, despite adequate intravascular filling pressures. Between 5% and 10% of patients with acute myocardial infarctions develop cardiogenic shock. A large proportion of these patients progress to shock not upon arrival, but more than 24 hours after initial presentation.¹² Overall mortality is approximately 60%, with very little improvement over recent decades. Treatments include fluids and inotropic agents to optimize myocardial contraction. Insertion of an intra-aortic balloon counterpulsation pump (IABP) can improve coronary perfusion by diastolic augmentation of perfusion pressure. This can have a profound impact by improving contractile function of peri-infarct territories. Although there is significant afterload reduction afforded by the IABP, cardiac output typically increases by only 15% to 20%. Emergent salvage revascularization can reduce mortality, with sustained benefits seen over long-term follow-up.¹³ When shock persists despite using these aggressive strategies, consideration must be made regarding the patient's candidacy for mechanical circulatory support using ventricular assist devices or extracorporeal membrane oxygenation.¹⁴ While

TABLE 83.1**COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTIONS**

■ COMPLICATION	■ DIAGNOSIS	■ TREATMENT
Cardiogenic shock	Echocardiography, pulmonary artery catheter	Inotropes, intra-aortic balloon pump, VAD
Ventricular septal defect	Echocardiography, cardiac catheterization	Surgical ventricular septal defect repair
Papillary muscle rupture	Echocardiography	Surgical valve replacement
Ventricular free wall rupture	Echocardiography, ventriculography	Emergent repair of ventricular defect

these options may only be available in selected regional medical centers, durable long-term survival can be obtained in a highly selected patient population.¹⁵

Postinfarction Ventricular Septal Defect

A postinfarction ventricular septal defect (VSD) is an infrequent complication occurring after fewer than 1% of acute myocardial infarctions. The infarct is most commonly in the LAD territory, with the defect in the distal septum. Alternatively, a postinfarct VSD can form from acute right coronary occlusion, with the infarct predominantly in the posterobasilar septum. They typically present 5 to 10 days following initial presentation, but can occur earlier, particularly if late thrombolytic therapy was administered. The diagnosis should be considered in a patient in whom cardiogenic shock with refractory hypotension and pulmonary edema develops suddenly following a myocardial infarction. On physical examination, an unmistakable holosystolic murmur can be heard over the entire precordium. The diagnosis is confirmed with echocardiography using Doppler techniques to demonstrate flow across the interventricular septum. Right heart catheterization will reveal a step-up in oxygen saturation from the right atrium to the pulmonary artery. Medical therapy involves stabilization to optimize cardiac output and end-organ perfusion. Refractory hypotension is typical, excluding the use of afterload reducing agents. Intra-aortic balloon counterpulsation can occasionally be helpful for afterload reduction and to optimize coronary perfusion. Emergent surgical intervention is required if there is any hope of survival. Infarcted muscle is debried, and the defect is typically closed using prosthetic material. For surgical candidates, survival rates of approximately 50% can be expected.¹⁶

Papillary Muscle Rupture

Severe regurgitation of the mitral valve can occur after acute myocardial infarctions, with a frequency of less than 1%. The mechanism is related to infarction of the tip or trunk of one of the papillary muscles, with resultant disruption of the mitral subvalvar apparatus and failed leaflet coaptation. Posteroinferior MIs lead to this complication two to three times more frequently than anterior infarctions, presumably because there is more collateral blood flow to the anterolateral papillary muscle compared to the posteromedial. While chronic mitral regurgitation can be well tolerated through adaptive changes in the left atrium and pulmonary vascular bed, severe acute mitral regurgitation results in immediate heart failure, as the small left atrium offers little compliance for the massive volume overload. Papillary muscle rupture develops typically between the third and fifth days following myocardial infarction,

when infarcted myocardium is at its weakest. However, it can present within the first 24 hours. Patients will describe acute-onset dyspnea, pulmonary edema, and possibly signs of cardiogenic shock. The diagnosis should be suspected in any patient after myocardial infarction with a new holosystolic murmur heard at the apex, associated with dyspnea and hypotension. Bedside surface echocardiography typically demonstrates the mitral regurgitation, and the flail leaflet may be seen. For more definitive imaging, transesophageal echocardiography (TEE) can be performed. Not only will the mitral valve pathology be clearly seen, but also alternative diagnoses such as a postinfarct VSD can be excluded. In addition to the treatments typically employed for myocardial infarctions, immediate medical therapy of ruptured papillary muscles involves afterload reduction when tolerated, with infusions of nitroglycerin or nitroprusside. If cardiac output cannot be maintained, intra-aortic balloon counterpulsation can be helpful. Definitive therapy involves prompt surgical correction. Although mortality rates are generally high, there are no survivors without surgical correction.¹⁷ If coronary angiography demonstrated occlusive epicardial lesions in territories other than the acute infarction, simultaneous coronary bypass grafting can be performed. Under most circumstances, the diseased mitral valve is excised and replaced. Because the ventricular cavity is typically small, the valve is usually replaced with a low-profile mechanical prosthesis to avoid left ventricular outflow obstruction from the protruding struts of stented bioprosthetic valves.

Ventricular Free Wall Rupture

Ventricular free wall rupture after myocardial infarction is infrequently encountered clinically, likely because of the exceedingly high mortality. The actual incidence is unknown, but may represent up to 30% of all deaths after acute myocardial infarctions. Like postinfarct VSD and papillary muscle ruptures, they tend to occur between the third and sixth days after infarction, when the myocardium is at its weakest. Free wall ruptures can present in essentially one of two ways: (a) a simple full-thickness tear with catastrophic hemorrhage and death from tamponade or (b) a complex serpiginous tear, partially contained. The latter is more likely to require surgical intervention, often presenting weeks from the initial infarction with symptoms of delayed cardiac tamponade. In rare cases, it is completely contained and may go unrecognized until a pseudoaneurysm develops, which is often diagnosed at a later date. Patients with free wall rupture will typically present with cardiogenic shock and may have features suggesting tamponade. Echocardiography will demonstrate a large pericardial effusion, frequently with echo-dense clot or ventricular wall defects. Urgent surgical intervention is required, often without coronary angiography or other time-consuming diagnostic tests. Once the pericardium is opened and cardiac tamponade is relieved, hemodynamic stability is often

FIGURE 83.3. The electrocardiogram in an acute myocardial infarction.

achieved. The site of hemorrhage is identified by the necrotic-appearing myocardium and adherent thrombus. The defect can be closed with large mattress sutures reinforced with Teflon felt strips. Care must be taken while tying the suture, as the necrotic muscle is weak and friable. Some have advocated covering the defect with a large Teflon felt patch using biologic adhesives, avoiding sutures altogether.¹⁸ Whatever the technique, outcomes are likely determined by the hemodynamic status of the patient prior to arrival in the operating room and the quality of the remaining viable myocardium.

DIAGNOSIS

The initial diagnostic tool for patients presenting with chest pain is the resting electrocardiogram (ECG). Although the majority of patients with chronic stable angina will have a normal ECG pattern, evidence of previous myocardial infarctions may be identified, either with the presence of Q waves or conduction abnormalities. Patients with an acute myocardial infarction may demonstrate ST-segment elevation (Fig. 83.3),

prompting urgent intervention. Occasionally, more subtle ECG findings may provide clues that the chest pain is ischemic in etiology. Although nonspecific, these changes may include mild ST-segment depression or T-wave inversions.

During a myocardial infarction, the dying myocytes release enzymes specific to cardiac muscle into the bloodstream. These enzymes can be detected from laboratory analysis and are pathognomonic of myocardial infarction. The MB fraction of creatine kinase is cardiac specific and rises within 8 to 24 hours of infarction and returns to baseline within 2 days. Cardiac troponin has even greater specificity and serum levels rise faster than creatine kinase, improving both the speed and accuracy in the laboratory diagnosis of an acute myocardial infarction in the absence of clear ECG changes.¹⁹

For asymptomatic patients, or those with chronic stable angina, the most widely used diagnostic test to evaluate for coronary artery disease is exercise electrocardiography, or a “stress test.” Using standardized protocols, patients are exercised on a treadmill while the 12-lead ECG is continuously recorded. Alternatively, for those patients unable to walk, a bicycle ergometer may be used. Testing is continued until patient symptoms are noted or until the development of significant downward-sloping ST-segment depression, suggesting myocardial ischemia (Fig. 83.4). The diagnostic accuracy of exercise stress ECG testing can be enhanced with myocardial perfusion imaging. Several radioactive tracers are used clinically, the most frequent of which is thallium-201. Because of its similarities to potassium ions, it is taken up preferentially by viable cardiac myocytes. Its distribution within the myocardium is proportional to the rate of perfusion. During stress, regions of underperfused myocardium will take up less thallium, resulting in a visible defect. Following a period of rest and reperfusion, thallium uptake normalizes, demonstrating a “reversible defect.”

In some cases, patients are unable to exercise because of additional physical or psychological limitations. Pharmacologic agents can substitute for exercise by increasing myocardial oxygen demand (dobutamine) or by directly vasodilating coronary arteries (adenosine or dipyridamole), thus demonstrating regions with fixed restrictions in myocardial blood flow. Echocardiography can be used as an alternative to nuclear perfusion imaging to improve the accuracy of exercise ECG testing. Regional changes in wall motion will be observed during myocardial ischemia, followed by restoration of normal myocardial contraction after rest or discontinuation of dobutamine. Echocardiography can also identify valvular abnormalities or other conditions that may influence treatment choices.

Coronary angiography, also known as cardiac catheterization, is the definitive tool for diagnosing coronary atherosclerotic

FIGURE 83.4. Electrocardiogram during an exercise test showing precordial leads V₁ through V₆. A: During exercise, depression of the ST segment and ischemia are seen in leads V₄ through V₆. B: These resolve after exercise is stopped.

disease. Indications include symptomatic patients with typical angina refractory to medical treatments, patients with significant ischemia on exercise or pharmacologic stress testing, patients with an STEMI, or patients with an NSTEMI and persistent pain despite medical treatment. Patients with valvular heart disease who are scheduled to undergo surgical correction should also undergo coronary angiography to identify coexisting coronary occlusions, which can be addressed at the time of the valve surgery. After percutaneous access is obtained in the femoral, brachial, or radial arteries, preformed catheters of varying sizes are advanced fluoroscopically to selectively engage the ostia of the left and right coronary arteries. Radio-opaque contrast is injected with imaging of the opacified coronary artery. Standardized views are obtained of both the right and left coronary systems to provide different projections to clearly define the vascular anatomy and to quantify the severity of occlusive lesions (Fig. 83.5). Automated computer analysis systems can calculate area reduction, improving interobserver

consistency. Additionally, catheters can be inserted across the aortic valve into the left ventricular cavity, providing information about ventricular pressure throughout the cardiac cycle. Contrast injection for ventriculography can illustrate ventricular systolic function, cavity size, and the presence of left-sided valvular abnormalities. New microtipped pressure sensors can be advanced across coronary lesions and document a clinically significant drop in perfusion pressure, either at rest or after provocation with vasodilating agents.²⁰ In addition, intravascular ultrasound imaging sensors can now be loaded onto tiny catheters and advanced into the left main coronary artery, helping to clarify the significance of lesions that may appear equivocal in severity on standard angiography.²¹

Newer imaging techniques using high-resolution multislice computed tomography (CT) scanning with three-dimensional reconstruction and magnetic resonance imaging are increasingly being utilized. These noninvasive approaches have the potential to improve the safety and convenience of coronary imaging;

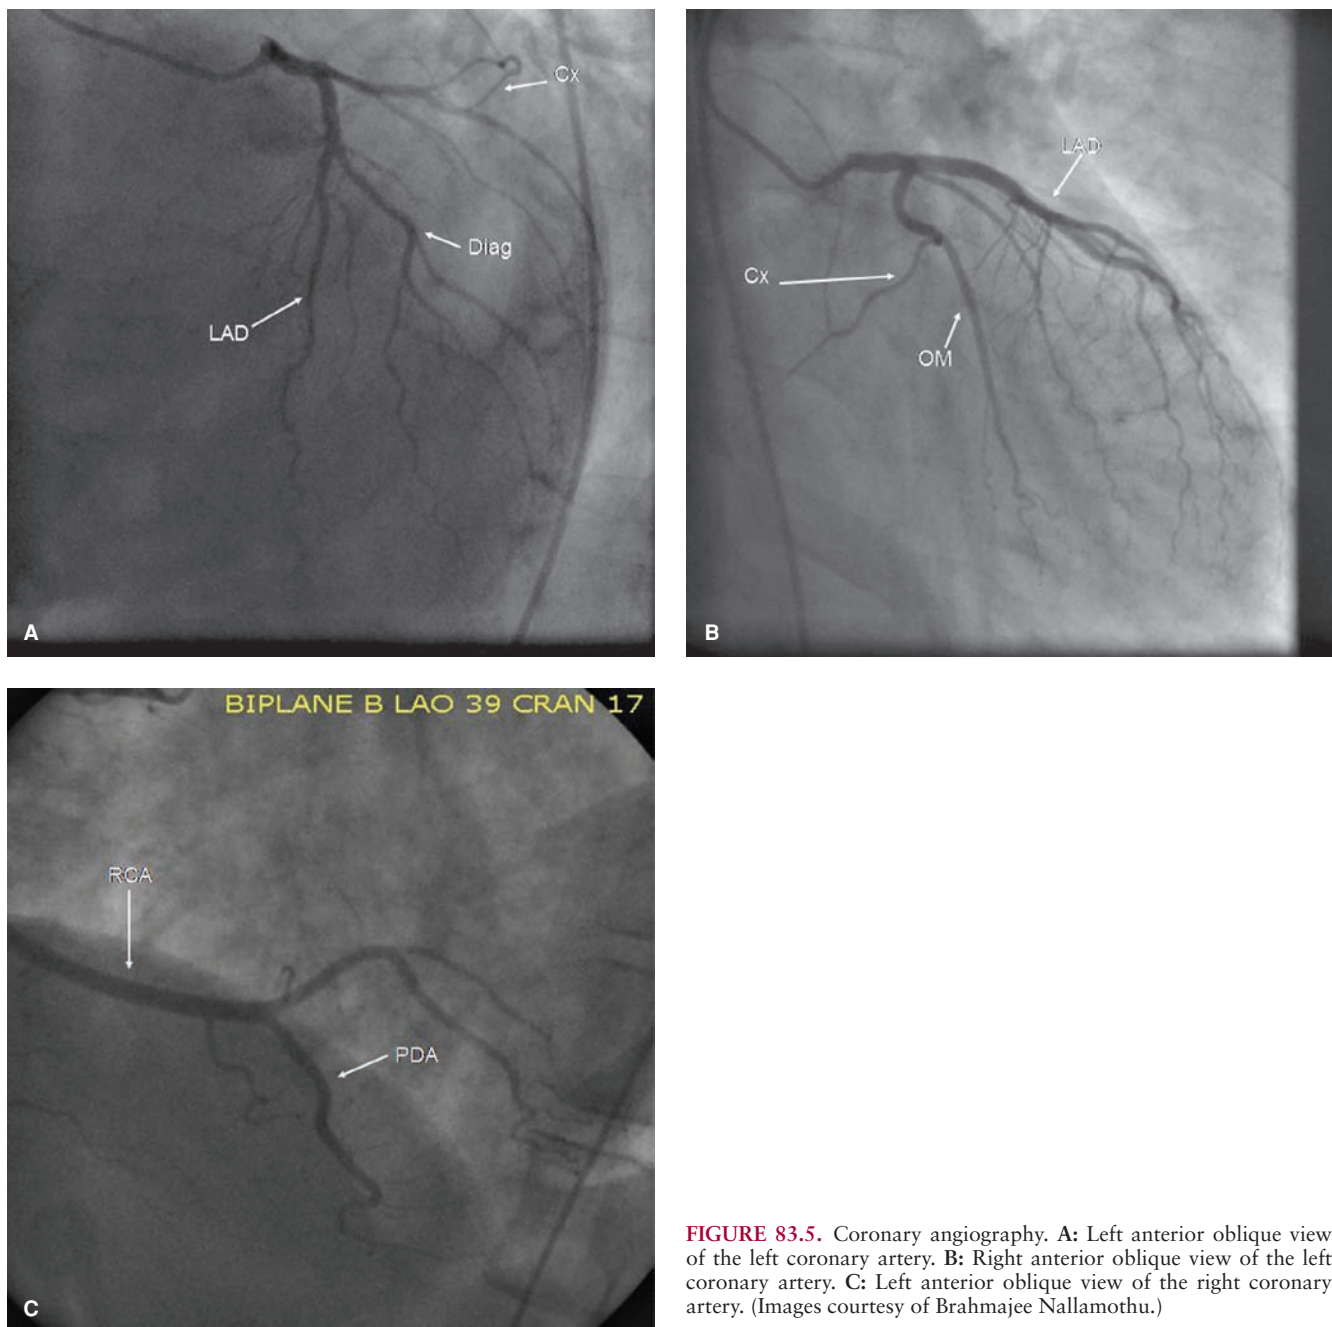

FIGURE 83.5. Coronary angiography. A: Left anterior oblique view of the left coronary artery. B: Right anterior oblique view of the left coronary artery. C: Left anterior oblique view of the right coronary artery. (Images courtesy of Brahmajee Nallamothu.)

however, resolution remains inferior to standard coronary angiography. These techniques are often used as screening tests and are frequently followed up with traditional angiography.²²

MEDICAL TREATMENT

- 5 Medical therapy of coronary artery disease is designed to slow the rate of progression of coronary artery atherosclerosis, to reduce the rate of complications from these lesions, and to control symptoms. Treatments are aimed at slowing plaque growth, reducing risk of plaque rupture, and reducing myocardial oxygen consumption. While advances in pharmacologic agents have improved the treatment of atherosclerosis and reduced mortality, lifestyle modification remains the most important intervention and the most difficult to achieve. These lifestyle modifications include cessation of cigarette smoking, weight loss, dietary control of diabetes, salt restriction, reduction in the consumption of foods high in cholesterol and fat, and exercise.

Medical therapy begins with controlling risk factors that contribute to formation and destabilization of the atherosclerotic plaque. Medical treatment alone is often satisfactory for many patients with coronary artery disease affecting only one or two epicardial vessel territories. Statins can decrease cholesterol levels and improve the ratio of low- to high-density lipoproteins and have been demonstrated to reduce rates of myocardial infarction and death.²³ Statins also appear to reduce macrophage accumulation within atheromatous plaques, matrix metalloproteinase activity, and collagen degradation. Angiotensin-converting enzyme (ACE) inhibitors have been shown to reduce mortality and myocardial infarction in patients with coronary artery disease.²⁴ Aspirin inhibits cyclooxygenase-1 (COX-1) activity and thromboxane production, irreversibly inhibiting platelet aggregation by inhibiting platelet activity, and should be prescribed to all patients unless significant contraindications exist. Aspirin has been shown to reduce death and myocardial infarctions in patients with significant coronary artery disease. By binding the catecholamine-mediated B1 receptor on cardiac myocytes, beta-blocking agents reduce myocardial oxygen consumption by reducing heart rate and contractility, and increase perfusion by extending diastolic perfusion time. Beta-blockers are effective at controlling angina²⁶ and, in selected patients, reduce cardiovascular mortality.²⁷ Nitrates also reduce myocardial oxygen demand by decreasing cardiac preload via venodilation and by reducing afterload via arterial vasodilation. Some epicardial coronary vasodilation will occur, improving coronary blood flow. Nitrates can be given sublingually for immediate relief or as an oral long-acting agent for continuous control of symptoms. Headaches and tolerance are notable side effects. For patients who have refractory angina despite all revascularization and traditional medical options, a newer agent, ranolazine, has recently been introduced. It alters cardiac myocyte membrane ion channel permeability and can relieve angina with few side effects.²⁸

A patient admitted to the hospital with a diagnosis of acute myocardial infarction or possible acute coronary syndrome should be placed in an environment with continuous ECG monitoring and the capacity to perform emergent defibrillation, since these patients are at risk of life-threatening malignant ventricular arrhythmias. Patients with evidence of ST-segment elevation should undergo emergent cardiac catheterization when possible, as will be discussed later. For those patients in which the ECG is normal but an acute coronary syndrome is suspected, a stress test should be performed expeditiously to identify their risk for future coronary events and to identify patients in need of urgent cardiac catheterization.

Unless there is a strong contraindication, aspirin should be administered immediately, ideally chewed to increase the rate of bioavailability. Typically, aspirin is given by emergency transport personnel. Patients may be instructed by 911 operators to take aspirin if they describe chest pain. Institution of

oxygen therapy is important to maximizing oxygen delivery, particularly for patients in whom hypoxemic respiratory dysfunction is also present. Intravenous nitroglycerine as a continuous infusion is typically effective at controlling symptoms of pain, which is essential in reducing unnecessary myocardial strain. Small randomized trials have suggested that nitroglycerine can reduce hospital mortality, although this has not been validated in larger trials.²⁹ When necessary, narcotics should be added, as unrelenting pain not only increases myocardial oxygen consumption, but also may contribute to plaque instability. Beta-blocking agents can reduce myocardial oxygen consumption but can also exacerbate heart failure, particularly in the setting of severely decreased systolic ventricular function. They should be considered cautiously in hemodynamically stable patients. ACE inhibitors reduce mortality after acute myocardial infarctions, particularly those with decreased ventricular function.³⁰ Benefits are not just restricted to the afterload reduction effects. Some evidence suggests they have a role in alteration of the myocardial intercellular matrix and scar formation.³¹

Anticoagulation is among the most important interventions in patients presenting with an acute myocardial infarction. In recent years, patients with myocardial infarctions were placed on newer antiplatelet glycoprotein (Gp) IIb/IIIa inhibitors, which affect adenosine diphosphate (ADP)-mediated platelet adhesion. Thienopyridines are a newer class of antiplatelet agents that act by binding to the ADP receptors on the platelet surface and inhibiting the GpIIb/IIIa pathway. Specific agents include clopidogrel (Plavix) and ticlopidine (Ticlid). There is strong evidence that the addition of clopidogrel to aspirin reduces death, myocardial infarction, and stroke in the setting of ACS.³² Clopidogrel is irreversible and has a long half-life, resulting in bleeding complications, particularly if surgery is required. Surgical intervention should ideally be delayed for 3 to 5 days.³³ Abciximab (ReoPro) is a murine antibody that binds directly to the GpIIb/IIIa receptor on platelet surfaces, preventing fibrinogen binding and activation. The half-life is short, and platelet activity generally returns to normal within 24 hours. Eptifibatide (Integrilin) is a synthetic antagonist of the GpIIa/IIIb receptor and has a half-life of 3 to 4 hours. The benefit of these agents in patients with ACS treated medically is unclear, but they have become routine in the setting of percutaneous treatment of coronary stenoses. Unless contraindications exist, inhibition of the coagulation cascade is also recommended for patients with acute myocardial infarctions. Although standard unfractionated heparin has been used for many years, newer low-molecular-weight agents and direct Xa inhibitors may have advantages and are used with increasing frequency.^{34,35}

With STEMI, significant myocardium is at risk, potentially resulting in either cardiogenic shock or ventricular arrhythmias. Emergency recanalization of acutely occluded vessels can salvage cardiac function and save lives. Various fibrinolytic drugs, which convert plasminogen to plasmin, can be given emergently and restore flow in vessels obstructed by acute thrombus. A number of clinical trials were performed in the 1980s using streptokinase and demonstrated reduced survival when it was given within 12 hours.³⁶ Newer agents are now available including tissue plasminogen inhibitor (tPA) and reteplase, which are faster in onset and may further improve outcomes, although they are more costly.

The main drawbacks of fibrinolytic therapy are bleeding complications and failure of recanalization. Systemic intravenous thrombolytic therapy unquestionably decreases morbidity and mortality after MI and continues to be used in 40% to 50% of eligible patients. The earlier the treatment, the greater the impact, with the greatest benefit accruing in patients treated within 1 to 2 hours after the onset of symptoms.

In 1977, Dr. Andreas Gruentzig performed the first percutaneous intervention with balloon angioplasty on a stenotic lesion in the LAD. This pioneer laid the foundation for a revolution in the treatment of coronary artery disease worldwide.

Percutaneous treatment of acute STEMI is now standard practice in centers in which this therapy is available, with outcomes that are superior to pharmacologic reperfusion.³⁷ Although percutaneous intervention may be better than fibrinolysis, the treatment requires numerous experienced personnel and highly technologic equipment, which is not always available in every facility. Complex interhospital and intrahospital systems are now in place to improve the efficiency and application of this treatment strategy, and guidelines have defined minimum “door to balloon” times to salvage myocardium at risk.³⁸

PERCUTANEOUS CORONARY INTERVENTIONS

- 6 Since the inception of percutaneous transcatheter balloon angioplasty (PTCA), catheter-directed treatment of coronary

artery disease has evolved into one of the most commonly performed procedures worldwide. Advances in technology have improved outcomes and expanded the indications, particularly for the acutely ischemic heart. Using the same techniques described for cardiac catheterization, small, highly flexible and steerable guide wires can be advanced through the lumen of epicardial coronary arteries. Over this guide wire, balloon-tipped catheters can be advanced and centered across discrete stenotic lesions and inflated to 4 to 10 atmospheric pressures, stretching and dilating the affected vessel (Fig. 83.6). Typically, the vessel tears or cracks at the junction of the plaque and the normal vessel wall. Acute thrombosis or coronary dissection could result in immediate closure of the vessel, often necessitating emergent surgical coronary bypass grafting in approximately 5% of cases. Restenosis is common, occurring in nearly 40% to 50% of patients, either from mechanical elastic recoil or progressive neointimal hyperplasia.

FIGURE 83.6. Percutaneous coronary intervention. **A:** A stenotic midright coronary artery lesion. **B:** Balloon angioplasty. **C:** Postintervention result. (Images courtesy of Brahmajee Nallamothu.)

The addition of stents, nitinol scaffolding devices, has nearly eliminated acute vessel occlusion, and the need for salvage surgical revascularization is below 1%. In addition, stents have greatly reduced restenosis rates down to nearly 20% and are used in nearly 90% of percutaneous procedures in the United States. The stents are delivered crimped onto a deflated balloon. With balloon inflation, the stent expands, restoring the vessel lumen to its anatomic dimensions. The stent prevents elastic recoil and coronary dissection, improving immediate outcomes, but the problem of neointimal hyperplasia remains, resulting in the persistent rates of restenosis. Stents have been improved even further by impregnating antiproliferative drugs onto the scaffolds. Sirolimus and paclitaxel are immunosuppressants that act by different mechanisms. Paclitaxel is a mitotic inhibitor, which retards microtubule breakdown. Sirolimus binds intracellularly to FK-binding protein and inhibits interleukin-2 (IL-2) production via the target of rapamycin pathway. Both sirolimus- and paclitaxel-eluting stents have further reduced the rate of target vessel restenosis and the need for repeat interventions.³⁹ However, reports of late stent thrombosis have raised concerns, and indefinite use of antiplatelet regimens has been recommended.⁴⁰

CORONARY BYPASS GRAFTING

Indications

Coronary artery bypass grafting (CABG) is one of the most common and most studied surgical procedures performed in the United States. As one might expect, CABG consumes more resources than any other single cardiovascular procedure. Dozens of multicenter, prospective, randomized trials have been performed comparing the surgical treatment of coronary artery disease to both medical and percutaneous options. Some of these landmark studies will be discussed in detail later in the chapter, as proper understanding of these trials is important in determining appropriate treatment strategies for individual patients. In summary, these studies consistently demonstrate that CABG continues to be the best revascularization strategy, reducing rate of both myocardial infarctions and the need for repeat revascularization in patients with a broad degree of occlusive disease. A task force made up of numerous medical societies including the American College of Cardiology, the American Heart Association, the Society of Thoracic Surgeons, and the American Association of Thoracic Surgeons recently

published guidelines on the indications for coronary artery revascularization and made recommendations regarding the mode of revascularization.⁴¹ The group considered a number of variables, including clinical symptoms and mode of presentation, the degree of ischemia determined by noninvasive imaging, and the severity of coronary disease based on angiographic imaging. In summary, patients are more likely to benefit from surgical revascularization if they have worse symptoms, more severe myocardial ischemia, and more extensive coronary artery occlusions. The recommendations are summarized in Figure 83.7, where recommendations are categorized as “appropriate,” “uncertain,” and “inappropriate.” Interestingly, these guidelines have not changed markedly over the last several decades, despite vast improvements in both medical treatment and percutaneous technology. Today, CABG remains the best mode of cardiac revascularization in symptomatic patients.

Standard Technique

7 The basic principles in coronary bypass grafting are to restore normal unimpeded perfusion of ischemic myocardial territories by providing alternative routes for blood flow. Previous approaches to surgically revascularize the myocardium included creation of intramyocardial tunnels and arterialization of the coronary sinus. However, it was the aortocoronary bypass pioneered by a surgeon named Rene Favaloro at the Cleveland Clinic in the late 1960s that revolutionized the treatment of coronary atherosclerosis. The technique has evolved considerably over the decades, and there remains significant variability in how this complex procedure is conducted even today.

The heart is typically exposed via a median sternotomy. This incision allows exposure of the anterior surface of the heart, as well as the great vessels, for initiation of cardiopulmonary bypass. Except for the severely hypertrophic heart, the entire epicardial surface can be exposed with manipulation and traction on the left ventricle. Alternatively, a left lateral thoracotomy can be used. This limits visualization to the obtuse margin of the heart but can be advantageous, particularly if the patient has previously had a median sternotomy with dense adhesions hazarding catastrophic injury during sternal reentry. Another alternative has been a limited left anterior thoracotomy, which exposes only a small portion of the anterior wall of the left ventricle, usually limited to revascularization of the LAD. This approach will be discussed later in the section

describing minimally invasive approaches to surgical revascularization.

The key to constructing a durable and reproducible anastomosis to small diseased epicardial vessels is creation of a quiet and bloodless surgical field. The advent of cardiopulmonary bypass (CPB) using extracorporeal circulation along with cardiac standstill using cardioplegia has allowed precisely this environment. The epicardial vessels are motionless and can be brought directly into the surgical field. Epicardial blood flow is eliminated, allowing direct visualization of the lumen without arterial control, avoiding potential clamp or snare injury to the fragile vessels.

After anticoagulation with 300 IU/kg of heparin is confirmed with an activated clotting time (ACT), the patient is cannulated in the distal ascending aorta. Patients may have significant atherosclerotic disease, and the cannulation site should be carefully inspected for mobile lesions using transesophageal echocardiography and manual palpation. Some centers advocate epiaortic ultrasonic imaging for more accurate visualization. After insertion, the cannula is manually deaired and connected to the arterial limb of the CPB circuit (Fig. 83.8). Venous drainage is accomplished with a cannula in the right atrium, typically in the atrial appendage. Bleeding from the cannulation sites is controlled by pursestring sutures around the cannulas. Bypass is initiated by venous drainage into a reservoir, emptying the heart of venous return. Blood is pumped into a membrane oxygenator and returned into the aortic cannula, typically at a blood flow rate of 2.4 L/min per m² of body surface area. With full flow, ventilation of the patient can be discontinued, further improv-

ing visualization and minimizing motion in the surgical field. The extracorporeal blood is cooled, creating mild hypothermia, varying from 28°C to 32°C. Systemic cooling minimizes end-organ injury from relative hypotension or hypoperfusion from nonpulsatile blood flow.

After adequate cardiopulmonary bypass is confirmed, the heart is arrested by applying a clamp across the midascending aorta, proximal to the aortic cannulation site. This clamp isolates the native coronary vessels from the remainder of the systemic circulation. Cardioplegia is then delivered to the myocardium via a needle or catheter in the aortic root. There are a variety of cardioplegia solutions commercially available, but the most important components are dilute blood, cold temperature (8°C to 15°C), potassium at 15 to 30 mM/L, citrate for calcium binding, dextrose for myocardial substrate, and pH buffers. The cold temperature and potassium maintain the heart in diastolic arrest, reducing myocardial oxygen consumption. Cardioplegia is typically delivered intermittently, approximately every 15 to 20 minutes, to provide adequate oxygen and nutrient delivery and to minimize myocardial activity. Additionally, some surgeons utilize cardioplegia delivered in a retrograde fashion via a specially designed balloon-tipped catheter inserted into the coronary sinus. Protocols relying entirely upon antegrade delivery of cardioplegia hazard incomplete myocardial protection, particularly in territories of severe coronary artery stenosis or total occlusions. In addition, an incompetent aortic valve will limit cardioplegia delivery down the coronaries, and leaking into the left ventricle will result in significant ventricular distention. Furthermore, antegrade cardioplegia

FIGURE 83.8. Instrumentation for cardiopulmonary bypass.

can be delivered under supraphysiologic pressures from the extracorporeal mechanical blood pumps. This can result in epicardial vessel injury and embolization of atheromatous debris, particularly in the reoperative setting in which old vein grafts often contain mobile and highly friable lesions. The use of retrograde cardioplegia can overcome these limitations, and some evidence suggests outcomes can be improved.

Conduits used for coronary bypass grafting are variable. The oldest and most frequently chosen conduit is the greater saphenous vein because of its availability, accessibility, reasonable size match, the facility with which vascular anastomoses can be created, and the avoidance of morbidity in harvesting the vein. The adequacy and size of the vein can be assessed preoperatively using ultrasound techniques. Generally, a conduit of 2 to 4 mm in diameter is considered suitable. Alternative veins, such as the lesser saphenous vein and cephalic vein, are infrequently used for coronary bypass grafting because patency rates have been reported to be low. The greater saphenous vein can be exposed with a single long incision, beginning at the ankle, midway between the medial malleolus and the anterior tibial tendon. It is important to handle the vein gently and avoid electrocautery directly on the vein to minimize traumatic or thermal injury to the endothelial cells. The side branches are carefully ligated, and the vein is preserved in a solution of cold heparinized blood, often with vasodilating agents such as papaverine and nitroglycerine. If dissection is minimized and hemostasis is meticulously ensured, the incidence of infection and wound healing complications is generally low. Patients will complain of pain along the length of the incision, but this typically resolves after several weeks.

In more recent years, minimally invasive approaches using endoscopic techniques can harvest the entire length of the greater saphenous vein with three small incisions. After exposure of the vessel at the knee, a blunt dissector is used to create a tissue plane, which is then expanded with CO₂ insufflation. Direct visualization with magnifying endoscopic lenses allows identification and ligation of side branches (Fig. 83.9). The dissection proceeds both proximally and distally, until the vein has been fully mobilized. Small stab incisions allow ligation at the groin and the ankle, and extraction of the vein from the initial incision. This technique has reduced pain, has improved patient satisfaction, and appears to reduce hospital readmission from wound healing complications. However, the technique is more time consuming, which can be aggravating for the impatient surgeon. In addition, the disposable equipment is

expensive, increasing the costs by approximately \$500 to \$1,000, depending on the manufacturer and negotiated contract pricing. More importantly, a recent nonrandomized report described the use of endoscopic vein harvesting as an independent predictor of vein graft occlusion, hospital readmission for major cardiac adverse event, and mortality, as compared to open saphenous vein harvesting techniques.⁴² This study was in contrast to the previous smaller randomized trials but raises concerns about the use of this strategy. Proponents of endoscopic vein harvesting argue that the observational trial did not describe the operator's previous experience using minimally invasive harvesting and suggest that many centers remained on the early part of their learning curve. In addition, newer technology now allows for safer delivery of bipolar electrocautery, minimizing the potential for heat transmission and endothelial injury. In addition, many centers are now administering low doses of heparin before initiating the dissection to reduce the likelihood of in situ thrombus during manipulation of the vein. It is likely that the debate regarding minimally invasive saphenous vein harvesting will continue in the near future.

Arterial conduits for coronary bypass grafting have been increasingly utilized because of early neointimal hyperplasia and late accelerated atherosclerosis seen in saphenous vein grafts. The most important of these arterial conduits is the left internal mammary artery, which originates from the left subclavian artery and descends caudally behind the chest wall, just lateral to the sternal edge. It gives off intercostal branches until it terminates distally as the bifurcation into the superior epigastric and musculophrenic arteries. The artery is typically mobilized as a pedicle, left intact at its origin from the subclavian artery. After completion of the median sternotomy, the left hemisternum is retracted anteriorly using an elevating self-retaining retractor (Fig. 83.10). Under direct visualization, the mammary artery, its accompanying paired veins, and a small swath of chest-wall soft tissue are gently separated from the remaining chest wall. Intercostal branches are controlled with clips and divided sharply or with cautery. The dissection proceeds proximally to the subclavian vein and distally to the terminal bifurcation of the internal mammary. A helpful marker identifying the distal extent of the dissection is the appearance of muscular transverse thoracic fibers. Caution must be taken during the proximal extent of the dissection, as the phrenic nerve traverses close posteriorly to the origin of the left internal mammary artery. Once fully mobilized, the internal mammary is divided at the distal bifurcation after heparinization

FIGURE 83.9. Endoscopic vein harvesting. **A:** Endoscope is inserted through a small incision in the knee. **B:** Excellent visualization of the saphenous vein with ample working space. (Images courtesy of Maquet.)

FIGURE 83.10. Elevation of the left hemisternum for visualization of the left internal mammary artery.

and soaked in a solution of vasodilating agents to overcome spasm from manipulation.

Other arterial conduits are also increasingly utilized, such as the right internal mammary artery, the radial artery, the gastroepiploic artery, and the inferior epigastric artery. The internal mammary artery tends to be spared of atherosclerotic disease, and its patency rates are excellent many years following bypass surgery. As such, many surgeons routinely harvest both internal mammary arteries to take advantage of this biologic privilege. However, utilization of both internal mammary arteries can devascularize the sternum and increase the risk of postoperative sternal wound infections, particularly in obese diabetics.⁴³ The radial artery can be harvested safely in the majority of patients, as a complete palmar arch allows collateral flow to the hand from the ulnar artery. Preoperative ultrasound in addition to a bedside Allen test can reliably identify patients in which hand ischemia precludes radial artery use. Although the radial artery is more resistant to late occlusions typical in saphenous vein grafts, it tends to be prone to spasm from competitive flow originating from subcritically stenosed native coronary vessels. Radial arteries should only be used on coronary targets with at least 70% proximal stenoses. The inferior epigastric artery has been used as an arterial conduit, but limitations in length and the need for an abdominal incision have diminished enthusiasm. The right gastroepiploic artery can be used, since it has more than adequate length after mobilization off of the greater curve of the stomach. It is left on its pedicle from the gastroduodenal artery and tunneled through a hole in the diaphragm. It is most frequently used to revascularize the posterior descending coronary branch, but will easily reach posterolateral branches as well. Patency has generally been reported to be excellent, but its widespread use is restricted by the additional morbidity of laparotomy and risks of intra-abdominal complications.

Once conduits have been harvested, cardiopulmonary bypass has been instituted, and cardioplegia infusion has resulted in adequate diastolic arrest, the heart is manipulated to expose the epicardial vessels of interest. Occasionally, the coronary arteries are in fact not on the epicardial surface but run within the epicardial fat or deep within the myocardium. This is common for intermediate branches and the LAD. Careful dissection is often required. If the midportion of the LAD cannot be found, the vessel can be opened at the apex and a small coronary probe can be inserted proximally and palpated to better localize the vessel. Care must be taken to ensure the target has been properly identified. Even the most seasoned cardiac surgeons have mistakenly anastomosed grafts to epicardial veins. Once the target vessel is properly located, an appropriate site for anastomotic construction should be identified. It is

FIGURE 83.11. Distal coronary anastomosis with saphenous vein conduit. Excellent visualization in a quiet bloodless field is required to achieve a hemostatic and unobstructed graft.

important to have a thorough understanding of the angiographic location of significant obstructions to ensure the graft is bypassing all significant lesions. The anastomotic site should ideally be relatively spared of atherosclerotic disease, although in patients with advanced diabetes this is not always possible. The vessel is dissected using a #64 sharp scalpel and opened vertically in the midline. This maneuver is among the most essential and challenging, and requires precision and experience. Eccentric incisions, inadvertent incisions in the posterior wall, or incisions in friable plaques can result in stenotic or leaky constructions. The arteriotomy is extended using fine Potts scissors 3 to 4 mm in length. The conduit is beveled to the appropriate length and the anastomosis is created with a continuous running polypropylene suture, usually size 7-0 or 8-0 (Fig. 83.11). Absolute technical precision is crucial, and skills required for these distal coronary anastomoses take practice and experience. A motionless and dry surgical field, 2.5 to 3.5 magnifying loupes, experienced assistance, and a steady hand are essential. Some surgeons use gentle insufflation of CO₂ to clear the field of obscuring blood and to distend the coronary artery to improve visualization of the toe and heal. After completion of the anastomosis, saphenous vein grafts or free arterial grafts can be hand injected with cold saline to visualize patency of the vessel and competence of the construction. Pedicled arterial grafts can be opened, and flow down the target will be easily visualized.

The proximal ends of the grafts are usually connected to the ascending aorta. The grafts are cut to the appropriate length. This maneuver also requires experience, as a short graft will create tension, potentially impinging upon the distal anastomosis, and an excessively long graft may kink. The graft is distended to prevent twisting, and the aortic root is filled by infusing antegrade cardioplegia to help determine optimal graft length. One must take into account the change in geometry as the heart fills after weaning from cardiopulmonary bypass. In general, the conduits should take a straight trajectory toward their target (Fig. 83.12). An aortotomy is created using a specially designed punch of 4 or 5 mm diameter. The grafts are beveled, and the proximal anastomosis is created with continuous running 5-0 or 6-0 polypropylene. Alternatively, the aortic cross-clamp can be removed after completion of all of the distal coronary anastomoses, and a side-biting partial aortic clamp can be placed. This technique can reduce total cardioplegia time but may increase risk of atheroembolic complications from additional aortic manipulation.

After completion of all distal and proximal anastomoses and the aortic cross-clamp has been removed, the temperature

FIGURE 83.12. Bypass grafts take gentle curving but a direct approach to the coronary targets. The pericardium is typically left open to avoid kinking.

of extracorporeal circulation is warmed. Ventricular fibrillation often occurs but can easily be defibrillated with a single internal shock. Ventilation of the lungs is resumed, and CPB flow is gradually reduced. Careful inspection of myocardial contractility and volume is required during weaning, as transient dysfunction often occurs. It is important to avoid distention of ventricular chambers, which causes unnecessary increased myocardial strain. A period of empty beating reperfusion is often helpful, particularly if the aortic cross-clamp period was prolonged or if the heart was severely ischemic preoperatively. Temporary sinus node or atrioventricular node conduction abnormalities are common, and it is standard to place temporary pacemaker leads on the ventricle, although permanent conduction abnormalities are very rare. Suture lines should be inspected for hemostasis, and cannulas for cardiopulmonary bypass are removed. Although not essential for routine CABG, pulmonary artery catheters and transesophageal echocardiography are helpful in weaning from CPB. Excessive pulmonary artery pressures or new regional wall motion abnormalities can suggest perfusion abnormalities and should prompt careful inspection of the bypass grafts. Once satisfactory hemodynamics are achieved, protamine is administered to reverse the anticoagulation of heparin. A notch in the pericardium to the left of the pulmonary artery must be created to allow unhindered passage of the pedicled left internal mammary artery to its distal target. The pericardium is typically left open after coronary bypass grafting to avoid graft kinking or compression; however, mediastinal and thymic fat can be carefully placed over the aorta and proximal anastomoses to protect them from future sternal reentry. Drains are left within the mediastinum to collect shed blood, and the sternum is closed with steel wires, cables, or plates.

Off-pump Technique

While the use of cardiopulmonary bypass was essential in allowing safe and reproducible coronary anastomoses, it is now well understood that extracorporeal circulation incites a powerful inflammatory response, activating neutrophils and monocytes to release cytokines and inhibiting the clotting cascade and

platelet function. Occasionally, these inflammatory changes can produce clinically relevant capillary leak, pulmonary edema, renal dysfunction, hemodynamic instability, and coagulation dysfunction. In addition, iatrogenic cardiac arrest induced by cardioplegia can infrequently result in myocardial injury and dysfunction. In order to avoid some of these adversities, attempts to perform CABG without the use of CPB have become increasingly popular in the last decade. Interestingly, CABG was originally performed without CPB in the early 1960s; however, it was largely abandoned because technically sound anastomoses could not be reliably constructed. Newer technologies are now available that have made creation of surgical bypass grafts more feasible on the full and beating heart.

The heart is exposed via a median sternotomy, identical to the approach used for standard coronary bypass grafting with cardiopulmonary bypass. Additional sutures are placed deep within the posterior pericardium, which can be used to facilitate retraction of the heart anteriorly and rightward, exposing the anterior, anterolateral, and obtuse marginal surfaces. Typically, the vessel with the most severe occlusion is grafted first, since occlusion of the vessel will result in the least myocardial ischemia and revascularization of this territory may collateralize other regions and improve tolerance to alternate vessel occlusion. For saphenous vein and free arterial grafts, the proximal anastomoses are performed first to allow immediate revascularization of ischemic territories following completion of the distal anastomoses. A dose of heparin is administered, typically 150 IU/kg, and adequate anticoagulation is confirmed with an ACT. A partial occlusion clamp is placed on the ascending aorta for control. Alternatively, newer sealing systems allow clampless control of the ascending aorta during construction of the proximal anastomoses, and sutureless connectors are available that can variably create satisfactory graft-aorta constructs. Once the proximal connections are complete, the grafts are carefully cut to the appropriate length after identification of the anticipated sites of the distal targets.

Of the potential epicardial vessels, the LAD is the easiest to expose, since it lies anteriorly. Gentle retraction on the pericardial sutures, occasionally along with a pad placed behind the heart, will usually expose the vessel adequately. The diagonal branches are exposed with slightly further rightward retraction. The obtuse marginal vessels can be exposed with the help of a suction device placed on the apex of the heart and slowly and gently retracting the apex anteriorly and rightward. This maneuver must be performed carefully, as cardiac chamber and/or outflow tracts can become compressed. The anesthesiologist must be alerted to and familiar with these maneuvers, as temporary vasoactive infusions may be required. Exposure of the right coronary artery and its branches is often the most challenging. The right ventricle can become compressed with retraction superiorly. The suction apparatus placed on the acute margin can facilitate exposure, as can stiff retraction of the right-sided pericardial edges.

Once the epicardial vessel of interest is identified, a U-shaped epicardial suction stabilizing device is applied around the vessel (Fig. 83.13). This device can reduce myocardial motion in a small region of interest, maintaining reasonable contractility. Silastic tapes loaded on blunt needles are carefully encircled around the proximal and distal portions of the coronary artery and gently retracted for blood flow control. A variable degree of ischemia may be seen on the electrocardiogram and transesophageal echocardiogram. The vessel is dissected and opened in the same way as is done for on-pump techniques. If ischemia is pronounced, small shunts can be inserted in the arteriotomy and the silastic snares released to reestablish some distal flow. Continuous insufflation of CO₂ can reduce obscuring blood from the field. The anastomosis is constructed, and competency is assessed. Electrocardiographic normalization should be seen immediately, confirming graft patency. Once all the grafts are complete, protamine is given to reverse the anticoagulation effect of heparin. Hemostasis is confirmed and closure proceeds routinely.

FIGURE 83.13. Suction-stabilizing devices allow isolation and immobilization of epicardial coronary targets.

Despite early enthusiasm for off-pump coronary bypass surgery, concerns regarding long-term patency of bypass grafts have prompted investigation into its true benefits and general application. A large multicenter randomized trial recently published investigated short- and midterm outcomes of patients undergoing either standard coronary bypass surgery with cardiopulmonary bypass or off-pump bypass.⁴⁴ Over 2,000 patients referred for coronary bypass grafting were randomly assigned to undergo standard versus off-pump CABG. All patients were felt to be suitable candidates for both approaches, and all surgeons had previously completed a median of 50 off-pump procedures to ensure competency. The primary endpoints were morbidity and mortality at 30 days and 1 year, and secondary endpoints were graft patency and neuropsychologic testing. Thirty-day mortality was similar in both groups (1.6% vs. 1.2% in off-pump vs. on-pump, respectively; $p = 0.47$), as was the rate of perioperative stroke (1.3% vs. 0.7%; $p = 0.28$). However, at 1 year, there was a higher rate of cardiac death in the off-pump group (2.7% vs. 1.3%; $p = 0.03$). At 1 year, 65% of patients underwent routine cardiac catheterization, revealing a significantly reduced rate of graft patency in the off-pump group (82.6% vs. 87.8%; $p < 0.01$), particularly for saphenous vein grafts (76.6% vs. 83.8%; $p < 0.01$). Neuropsychologic testing was performed to attempt to quantify benefits from eliminating proposed neurocognitive dysfunction attributed to cardiopulmonary bypass. Fifty-four percent of randomized patients completed neuropsychologic testing at baseline and at 1 year, and interestingly, there were no significant differences observed from baseline to 1 year between off-pump and on-pump strategies. In summary, this important and well-conducted study showed no advantages and potential disadvantages of off-pump surgical revascularization in this selected cohort of patients. While there are valid criticisms of this study, these data certainly suggest that routine use of off-pump CABG is not superior, and perhaps should be reserved to selected populations. This author uses off-pump techniques for patients with a heavily calcified or atherosclerotic ascending aorta or those with severe renal or hepatic dysfunction.

In addition to off-pump CABG, a variety of “minimally invasive” approaches have been conceptualized. The minimally invasive direct coronary bypass (MIDCAB) involves creating a small left anterior thoracotomy. After entering the chest in the fourth intercostal space and resecting a portion of the fourth costal cartilage, a portion of the left internal mammary artery is

mobilized under direct vision. Using off-pump techniques and stabilizing equipment, the internal mammary artery is anastomosed to the LAD using conventional open instruments. Although experiences at selected single centers have described satisfactory patency and reduced cost, complications, and postoperative length of stay,⁴⁵ the MIDCAB has not achieved widespread application. Technical considerations and exposure have raised concerns about graft patency, and in the era of increased percutaneous intervention, very few patients are referred with isolated single-vessel disease. Some groups have advocated for a hybrid approach, in which the LAD is surgically grafted using the MIDCAB approach and the right coronary and circumflex branches are treated percutaneously.⁴⁶ Robotic systems, such as the da Vinci (Intuitive Surgical, Sunnydale, CA), benefit from high-definition three-dimensional video visualization and precise remotely controlled instruments with 6- or 7-degree freedom of motion. They have been increasingly used in noncardiac surgery, particularly in gynecology and urologic specialties. Some centers have begun using robotic technology to harvest the internal mammary artery along its entire length, followed by a MIDCAB, also known as robotically assisted CABG (RASCAB).⁴⁷ Others have gone one step further, performing complete coronary revascularization using robotic instruments: the totally endoscopic coronary artery bypass (TECAB).^{48,49} The procedure has been performed with or without cardiopulmonary bypass and cardiac arrest. Although in selected centers the procedure appears feasible, the widespread utilization of minimally invasive coronary artery bypass remains in question because of concerns regarding patency, particularly in light of recent evidence regarding off-pump surgery in general. Despite changes in technology, there has been little growth in minimally invasive coronary artery bypass procedures.

POSTOPERATIVE CARE

Most patients after undergoing coronary bypass grafting require very little physician intervention, particularly if the operation was conducted according to the preoperative plan. The use of clinical care pathways is now routine, and they have been demonstrated to reduce morbidity, cost, and length of hospital stay. However, complications can occur, which must be anticipated for early recognition and treatment.

Patients after cardiac surgery are routinely admitted to the intensive care setting. Most centers delay extubation until systemic warming is complete, typically within 4 to 6 hours. This also gives ample opportunity to ensure adequate hemostasis and hemodynamic stability. Many centers routinely use pulmonary artery catheters, or Swan-Ganz catheters, for assessment of intracardiac filling pressures as well as calculation of cardiac output. Cardiac output (CO) can be calculated in one of two ways: thermodilution or the modified Fick technique. Using thermodilution, room temperature saline of a known quantity is injected briskly into the right atrium. As the saline mixes with blood traveling through the right ventricle, blood is cooled. The blood temperature is then recorded in the pulmonary artery over time. A curve is generated, denoting the change in temperature from baseline, and the area under this curve is inversely proportional to the cardiac output (e.g., the higher the cardiac output, the lower the impact the small saline aliquot has on blood temperature). Clinicians should be aware that severe tricuspid regurgitation can interfere with the validity of the thermodilution technique, typically underestimating forward flow. The Fick technique relies on the principle of mass balance proposed by Adolph Fick in 1870. Oxygen consumption (VO_2) must equal the difference in oxygen content of arterial and venous blood times the cardiac output. Assumptions can be made about oxygen consumption at rest, and arterial and venous oxygen content (CaO_2 and CVO_2) can be calculated by the hemoglobin concentration and oxyhemoglobin saturation:

$$\text{CO} = \text{VO}_2 / (\text{CaO}_2 - \text{CVO}_2)$$

Goals for hemodynamic stability generally include maintenance of a mean arterial pressure between 65 and 75 mm Hg and a cardiac index of at least 2 L/min per m². Outcomes should be individualized, as a chronically hypertensive patient may require a higher arterial pressure to maintain satisfactory tissue perfusion, and a postoperative patient with bleeding from a tenuous aortic suture line may benefit from a more restrictive blood pressure approach. Hypotension is quite common following cardiac surgery and is often related to hypovolemia, as well as vasodilation from systemic warming and an inflammatory response from extracorporeal circulation with activation of vasodilatory mediators. Intravascular hypovolemia is extremely common in the immediate perioperative period. Causes are multifactorial and include capillary leak from inflammation, venodilation from warming, unrecognized and unreplaced blood loss, and excessive diuresis, particularly if osmotic diuretics such as mannitol are given during cardiopulmonary bypass. Patients may require 2 to 3 liters of fluid in the first several hours after surgery. Those with ventricular hypertrophy and diastolic dysfunction may require additional fluid to maintain cardiac output. Although not essential, the pulmonary artery catheter can be instrumental in guiding fluid resuscitation. While colloids, such as albumin and hetastarch, can reduce the total volume required to maintain stability, there are no prospective randomized data clearly demonstrating its superiority with regard to outcome benefits.

Vasoconstrictors are used to treat hypotension, but should only be initiated if the patient has been adequately fluid resuscitated and myocardial function and cardiac output is preserved. α -Agonists, such as Neo-Synephrine, will increase vascular tone without increasing contractility or heart rate and do not exacerbate dysrhythmias. Similarly, vasopressin has no effect on cardiac function, but uniquely will not increase pulmonary vascular resistance, as there are no vasopressin receptors in the pulmonary vascular bed. Additionally, vasopressin preferentially constricts efferent renal arterioles rather than afferent arterioles, resulting in maintained glomerular filtration and urine output. Norepinephrine, epinephrine, and dopamine are also frequently used to counteract a vasodilatory state. These catecholamines are also inotropic agents, which can be useful if myocardial function is depressed. However, they all increase heart rate and myocardial oxygen consumption and can be arrhythmogenic.

Myocardial dysfunction can occur from stunning after cardioplegic arrest, particularly if the cross-clamp period was long. This can be problematic if systolic function is severely depressed preoperatively. Inadequate myocardial protection from insufficient cardioplegia can also result in catastrophic and unrecoverable postoperative heart failure. Unless the heart is acutely ischemic at the time of surgery, it is unusual to expect immediate improvement in contractility after surgical revascularization. In fact, the acutely ischemic heart often tolerates cardiopulmonary bypass and cardioplegia poorly. Contractility can be globally severely depressed after emergent coronary bypass grafting in the setting of a sizable STEMI, especially if the patient was in preoperative shock. If cardiac dysfunction and low cardiac output are detected intraoperatively, careful assessment of bypass graft position and patency should be undertaken. This is especially true if new wall motion abnormalities are regional.

Once surgical problems have been corrected, efforts are made to optimize myocardial contractility. Inotropic agents will improve cardiac function and can be easily titrated to the desired effect. Catecholamines, such as dopamine, epinephrine, and dobutamine, are frequently used. All of these agents, through their effects on β receptors, will increase heart rate, predispose to arrhythmias, and increase myocardial oxygen consumption. Nonetheless, these agents are generally safe, particularly at low doses. Phosphodiesterase inhibitors, such as milrinone, also improve contractility and have less effect on heart rate or myocardial contractility. These agents are also vasodilators, and should be used with caution in patients who are hypotensive. Both catecholamines and phosphodiesterase

FIGURE 83.14. Intra-aortic balloon pump positioned within the descending thoracic aorta. The device must be positioned to not occlude the left subclavian artery or the abdominal aortic branches. (Images courtesy of Datascope Corporation.)

inhibitors exert their inotropic effects by increasing cytosolic calcium. For these agents to be effective, there must be adequate calcium stores. Infusion of supplemental calcium often potentiates the effect of both classes of drugs. Likewise, acidosis decreases the effectiveness of inotropic agents, and normalization of blood pH, either by replacement of sodium bicarbonate or hyperventilation, can have an immediate effect on myocardial function.

When postoperative ventricular dysfunction is entirely related to myocardial stunning, inotropes should be weaned within the first 24 hours. However, if postoperative cardiogenic shock is severe and refractory to high-dose inotropic infusions, insertion of an intra-aortic balloon pump should be considered. Positioned within the thoracic aorta (Fig. 83.14), balloon pump actuation is timed with the patient's electrocardiogram or arterial pressure tracing. Inflation occurs during diastole, augmenting coronary perfusion, and deflates during systole, reducing afterload and increasing cardiac output. Insertion of a ventricular assist device may be beneficial; however, many of these patients subsequently require heart transplantation, so careful patient selection is essential.

Postoperative bleeding is infrequent but can occur, especially when patients are taking irreversible platelet inhibitors. Output from mediastinal chest drains is monitored closely, and markers of coagulation are assessed. Coagulopathy should be corrected with appropriate blood component transfusions. Retransfusion of shed blood is generally avoided, as it may exacerbate coagulopathy. Return to the operating room should be considered if drainage exceeds 600 to 800 mL in 4 to 5 hours, without signs of slowing.

Inhibitors of plasminogen can be helpful in reducing postoperative coagulopathy and bleeding complications. There are three agents in this class of drug: ϵ -aminocaproic acid (Amicar, Xanodyne Pharmaceuticals, New Port, KY), tranexamic acid, and aprotinin (Trasylol, Bayer Leverkusen, Germany). The first two agents are synthetic binders of plasminogen or plasmin. Aprotinin is a naturally occurring serine protease inhibitor that can inhibit plasminogen, as well as many other proteases. Although meta-analysis suggested that aprotinin was superior to the other agents,⁵⁰ concerns regarding the safety of aprotinin have been raised, suggesting a higher incidence of renal failure⁵¹ and even mortality.⁵² A subsequent prospective randomized trial concluded that aprotinin was independently associated with a higher rate of death,⁵³ and as such its approval has been halted by the U.S. Food and Drug Administration.

There has recently been great enthusiasm for using a blood conservation strategy. Transfusion of as little as a single unit of packed red cells is independently associated with increased morbidity after coronary bypass surgery.⁵⁴ Efforts to minimize hemodilution using retrograde priming and hemofiltration can be very effective at reducing transfusion rates, but the most important adjunct to reduce blood usage is reduced transfusion triggers. Evidence exists that hemoglobin concentrations as low as 7 g/dL can be safe and are very well tolerated in intensive care unit patients.⁵⁵

Cardiac tamponade is an infrequent but feared complication that can be fatal and is often difficult to diagnose. The classic scenario is a patient with initially high chest drainage that suddenly ceases. The patient then insidiously develops oliguria, followed by low cardiac output and refractory hypotension. Signs such as bulging neck veins, elevated central venous pressure, pulsus paradoxus, and widened mediastinal silhouette on chest radiography may be variably present. Echocardiography can establish the diagnosis by demonstrating a pericardial effusion with right atrial and right ventricular compression. However, it is important to note that echocardiography cannot rule out the diagnosis. Timely diagnosis usually requires experience and a low index of suspicion. Treatment involves immediate return to the operating room, where removal of the obstructing fluid and clot results in immediate relief of constriction and normalization of hemodynamic parameters. When tamponade occurs late, it may be treatable with percutaneous drains if the pericardial fluid content is thin and without significant clot burden.

Atrial fibrillation is extremely common following CABG, with a frequency of 25% to 30%. Its occurrence is higher for older patients and those with lung disease, and after combined CABG and valve surgery, decreased ventricular function, prolonged aortic cross-clamp period, and more severe hypothermia. Interestingly, the rate of atrial fibrillation does not appear to be reduced after off-pump CABG.⁵⁶ It most frequently occurs between the second and fourth postoperative day, and can be precipitated by electrolyte imbalances, particularly hypokalemia or hypomagnesemia. If the rate is excessively high or the patient has significant ventricular hypertrophy, atrial fibrillation can result in hemodynamic compromise producing hypotension and oliguria. The most frequently used treatment for postoperative atrial fibrillation is amiodarone. It can achieve adequate rate control after an intravenous load of 150 mg in the majority of patients, with minimal effect on blood pressure or contractility. As a class III antiarrhythmic, amiodarone is also very effective at facilitating conversion to sinus rhythm. When given preoperatively, amiodarone can also reduce the rate of postoperative atrial fibrillation, although bradycardia is more common in protocols that use higher doses.⁵⁷ Beta-blocking agents are also effective at achieving rate control, and when given routinely preoperatively and reinitiated immediately after surgery, they have reduced the occurrence of atrial fibrillation.⁵⁸ Diltiazem is immediately effective at controlling rapid atrial fibrillation, and is typically given as a 5- to 10-mg load, followed by a continuous infusion of 5 to 10 mg/h. Although it is associated with hypotension, its short half-life makes this complication quite manageable. For atrial

fibrillation with rapid ventricular response refractory to amiodarone, beta-blockers, and diltiazem, it may be reasonable to add digoxin. This drug should be used with caution, because it is proarrhythmic. Drug concentrations should be followed and potassium levels maintained aggressively. If rapid ventricular response results in significant hemodynamic instability, electrical cardioversion should be performed. Cardioversion may also be considered if atrial fibrillation persists after 24 to 36 hours because of the risk of clot formation within the left atrial appendage. Cardioversion should not be performed if atrial fibrillation has been present for more than 48 hours. If atrial fibrillation is persistent, anticoagulation must be considered and weighed against the potential for postoperative bleeding complications. The vast majority of patients who develop atrial fibrillation after CABG will revert to sinus rhythm, and the complication rate is generally low. However, atrial fibrillation does increase the length of stay and cost of hospitalization, so efforts to reduce its incidence are necessary.

Deep sternal wound infection involving the bone occurs in approximately 0.5% to 1% of patients. Independent risk factors are obesity, diabetes, immunosuppression, use of both internal mammary arteries, chronic lung disease, and malnutrition. The most frequent organism is *Staphylococcus aureus*, although gram negatives can be seen in diabetics and immunosuppressed patients. Helpful preventative strategies include decontamination of nasal *Staphylococcus* species with mupirocin, preoperative Hibiclen wash, and tight postoperative glucose control. The diagnosis is established with sternal wound drainage and palpable sternal instability. Systemic antibiotics should be initiated and the patient returned to the operating room expeditiously for sternal débridement. Delay could result in mediastinitis with sepsis and shock. Under most circumstances, the chest wall is reconstructed with myocutaneous flaps based on the pectoralis and rectus abdominus muscles.

RESULTS OF CORONARY BYPASS GRAFTING

Overall, the mortality rate following coronary bypass grafting is between 2% and 3%. This number has been progressively declining despite rising median age and worsening severity of disease (Fig. 83.15). Improved outcomes can be attributed to advances in surgical technique, anesthetic approaches, preoperative timing and patient selection, sophistication of intensive care systems, and superior pharmacology, including antiplatelet agents, beta-blockers, and statins. Increased competition, both between cardiac surgeons and with percutaneous interventionists, and public reporting of data have undoubtedly improved efficiency and contributed significantly to better outcomes. Major morbidity is estimated to be 10% to 12%. Risk of stroke is approximately 1% to 2%, renal failure requiring renal replacement therapy is 0.5% to 1%, deep sternal wound infection is 0.5% to 1%, and need for urgent reoperation is 3% to 5%. Overall median length of hospital stay is approximately 6 days.

The Society of Thoracic Surgeons (STS) maintains a voluntary registry for cardiac surgery outcomes. Participation throughout the United States is extremely high, and the database is generally considered an excellent representation of cardiac surgery outcomes. Overall, coronary bypass procedures have increased in volume, although at a slower pace in recent years, presumably as a result of expanded medical and percutaneous treatments. In 2008, 163,000 isolated coronary bypass procedures were submitted to the STS database. With over 1.4 million individual cases embedded in the dataset, enormous information can be obtained regarding risk factors for mortality and morbidity. Independent predictors of death are listed in Table 83.2 and include coronary reoperation, preoperative shock, dialysis dependence, immunosuppressed state, advanced age, diabetes mellitus, nonwhite race, female

FIGURE 83.15. Unadjusted isolated coronary artery bypass operative mortality: 2000–2009. (This graph is reprinted from the Society of Thoracic Surgeons adult cardiac database 4th 2009 harvest report executive summary. <http://www.sts.org/documents/pdf/ndb2010/20094thHarvestExecutiveSummary.pdf>. © The Society of Thoracic Surgeons. gender, previous stroke, advanced heart failure symptoms, peripheral vascular disease, and chronic lung disease. While the presence of these predictors are not contraindications for coronary bypass grafting, these prognostic tools are helpful both in balancing potential benefits from predicted risks and in correctly informing patients, families, and referring physicians. There are two well-described predictive models that can be used to estimate risk of death following coronary bypass surgery. Each model has been created using large voluntary registry data, one from the Society of Thoracic Surgeons, and one created from the European registry from 128 hospitals across eight countries. Both models incorporate features related to the patients, the nature of their clinical presentation, and the planned operative intervention. Although far from

TABLE 83.2

INDEPENDENT PREDICTORS OF MORTALITY FOLLOWING CORONARY BYPASS PROCEDURES

■ VARIABLE	■ ODDS RATIO
Age	1.05 (1.05, 1.05)
African American race	1.34 (1.23, 1.45)
Chronic lung disease	1.41 (1.35, 1.48)
Diet controlled diabetes	1.15 (1.09, 1.21)
Insulin requiring diabetes	1.50 (1.42, 1.58)
First reoperation	2.76 (2.72, 2.91)
Immunosuppression	1.75 (1.157, 1.95)
Renal failure	1.88 (1.80, 1.96)
Shock	2.04 (1.90, 2.19)
Male gender	0.84 (0.80, 0.89)
NYHA class IV symptoms	1.15 (1.10, 1.20)

perfect, both models can be very helpful in determining patient selection and preoperative optimization and in tailoring the therapy to the unique clinical circumstances.

Another risk factor for death after coronary bypass grafting that is not included in either stratification model is incomplete revascularization. Incomplete revascularization refers to failure to construct a bypass graft to a territory natively perfused by a vessel with at least a 50% proximal stenosis. Under most circumstances, the revascularization is incomplete because target vessels were unsuitable for bypassing because they were small, inaccessible, or too heavily diseased. The differences observed are typically not apparent in 30-day survival but manifest as a reduced long-term prognosis. Although the angiographic appearance of potential coronary targets may suggest unsuitability, interpretation of vessel quality is extremely subjective and very difficult to quantify, which is why it has not been incorporated into the two large risk creation models. Nonetheless, the quality of the bypass targets should be considered when weighing the options for treatment of advanced coronary artery disease.

The purpose of coronary bypass surgery is to create unimpeded blood flow to ischemic myocardial territories. While short- and long-term mortality may reflect the adequacy of revascularization, bypass graft patency is a more precise assessment of the technical success of the operation. Patency rates are typically reported based on clinical trials in which routine angiography is performed at regular intervals, excluding biases from studies in which angiography is only performed in symptomatic patients. Saphenous vein grafts are hampered by a higher early graft loss, as much as 20% in the first year. Mechanisms include technical anastomotic problems, graft kinking, inadequate epicardial run-off, vein graft endothelial dysfunction from injury or chronic stasis, competitive flow from relatively unobstructed native coronary flow, and early development of neointimal hyperplasia. Late vein graft occlusion develops at a rate of approximately 5% per year from progressive native vessel disease and the development of accelerated vein graft atherosclerosis. Patency at 10 years is generally 40% to 50%. It remains to be seen if these outcomes improve with advances in statin and antiplatelet agents. As described previously, the internal mammary artery is generally spared of both atherosclerotic disease and early development of neointimal hyperplasia. Not surprisingly, its patency is vastly superior,⁵⁹ although these outcomes may be biased by the fact that the left internal mammary artery is typically placed on the LAD. The higher outflow of this target results in greater flow rates, reducing the risk of stagnation from limited run-off. In addition, its anterior location make it less likely to kink. Patency at 1 year is approximately 95%, and there is very little attrition over time, with 85% to 90% patency at 10 years. In fact, the use of the internal mammary artery is an independent predictor of long-term survival, presumably because of better graft outcomes.⁶⁰ The radial artery is generally intermediate to saphenous vein grafts and the internal mammary artery. Patency rates have been described as 90% at 1 year and 80% to 90% at 5 years. The radial artery is particularly prone to spasm from competitive flow, resulting in a patent but dysfunctional graft, referred to as a string sign. The radial artery should be avoided when stenotic lesions are less than 70%.

COMPARATIVE TRIALS

With the advent of coronary bypass surgery in the late 1960s, questions arose as to which patients are appropriate to offer this highly invasive and costly treatment. Three landmark randomized trials were constructed comparing CABG with medical treatment for a variety of patient populations. The Veterans Administration Cooperative Study,⁶¹ the European Coronary Surgery Study,⁶² and the Coronary Artery Surgery Study⁶³ all demonstrated that CABG improves survival as compared to

medically treated patients, and the benefits of CABG are enhanced by more severe disease, as well as left ventricular dysfunction. Although these trials are now more than 30 years old and medical and surgical treatments have evolved considerably, the principles continue to apply and are repeatedly described in more contemporary series.

Although these clinical trials definitively demonstrated the superiority of CABG over medical therapy for patients with advanced coronary artery disease, the advent and widespread adoption of intracoronary balloon angioplasty raised the possibility that a less invasive approach to revascularization may be as beneficial as the surgical approach. Several multicenter clinical trials were conducted comparing CABG with angioplasty for a variety of patient populations. The most notable of these studies was the Bypass Angioplasty Revascularization Investigation, or BARI trial.⁶⁴ A total of 1,829 patients were deemed eligible and were randomized to angioplasty or CABG in 18 centers across the United States and Canada. While there were no differences for in-hospital death or 5-year survival, the rate of repeat revascularization was significantly higher in the percutaneously treated patients. Only 8% of patients in the CABG group required repeat revascularization within the first 5 years, as compared to 54% in the angioplasty group. Although survival analysis was intention to treat, 31% of patients in the angioplasty group underwent subsequent CABG. Importantly, subgroup analysis demonstrated a survival advantage at 5 years for diabetic patients treated with CABG as opposed to angioplasty (80.6% vs. 65.5%; $p = 0.003$). The BARI study demonstrated that surgical revascularization was more durable and resulted in improved survival for diabetic patients with advanced coronary artery disease.

Angioplasty alone carries a restenosis rate of 30% to 40% from at least two mechanisms. One is entirely mechanical, related to elastic recoil, and is seen within weeks of intervention. The other mechanism is related to progressive neointimal hyperplasia, likely occurring as a result of local trauma. Intracoronary stents have reduced the restenosis rate and improved outcomes of percutaneous intervention. In the setting of these advances, several multicenter, prospective, randomized trials were performed, again with the hypothesis that percutaneous intervention would be superior or equivalent to surgical revascularization for patients with advanced coronary artery disease. Among the most prominent of these studies was the SoS, or Surgery or Stent, trial.⁶⁵ A total of 988 patients from 53 medical centers in 11 countries were enrolled based on eligibility criteria, including the presence of multivessel coronary artery disease. Patients were randomly assigned to receive either coronary bypass surgery or percutaneous intervention using intracoronary stents. At a median follow-up of 2 years, 20.7% of patients in the stent arm required repeat revascularization, as compared to only 6% in the CABG arm ($p < 0.001$). Surprisingly, there was also a survival advantage seen with surgery (mortality 4.5% vs. 1.6%, stent vs. surgery, respectively; $p = 0.01$). These mortality advantages persisted with a median follow-up of 6 years (10.9% vs. 6.8%; $p = 0.02$).⁶⁶ Consistent with previous clinical trials, the survival advantage was even more pronounced for diabetics (17.6% vs. 5.4%). The SoS trial was similar to other randomized trials comparing coronary stents with CABG with respect to superior rates of repeat revascularization. However, SoS was unique in describing a mortality benefit. Some have argued that enrollment criteria were much less stringent in SoS, enrolling sicker patients with more complex anatomic lesions. SoS may therefore better reflect “real world” practice.

Among the biggest limitations of bare metal intracoronary stents is the development of obstructing neointimal hyperplasia resulting in in-stent restenosis, which occurs at a rate of 15% to 30%. Recently, antiproliferative drugs have been incorporated into the platform of stents to inhibit this occlusive process. These drug-eluting stents have been demonstrated in prospective randomized fashion to reduce the rate of repeat revascularization, when compared to bare metal stents. Because of

improved outcomes using this new technology, a prospective, multicenter, randomized trial was conducted comparing coronary bypass grafting with a strategy using drug-eluting stents for patients with left main or three-vessel coronary stenosis.⁶⁷ Eighty-five centers in the United States and Europe enrolled patients who met these criteria and whose anatomic disease was determined by both the surgeon and interventional cardiologist to be amenable to either strategy. A total of 3,075 patients were enrolled, but only 1,800 patients were randomized, 897 to CABG and 903 to PCI with the Taxus drug-eluting stent (Boston Scientific). The remaining patients were not felt to be good candidates for both procedures, and 1,077 underwent CABG and 198 underwent PCI. Outcomes of these excluded patients were collected into a separate registry. Of the randomized patients, more patients in the PCI arm had major cardiac or cerebrovascular events at 12 months (12.4% vs. 17.8%, CABG vs. PCI, respectively; $p = 0.002$). The majority of these differences were seen in the rate of repeat revascularization (5.9% vs. 13.5%; $p < 0.001$). The authors also created a numerical system to comparatively describe the complexity of the coronary anatomy. This “syntax” score was higher for chronic total occlusions, bifurcation lesions, heavily calcified vessels, and lesions greater than 20 mm in length. The differences in major cardiac or cerebrovascular events between CABG and PCI were even more pronounced in the subgroup of patients with a high “syntax” score (10.9% vs. 23.4%). This study once again demonstrated that despite improved outcomes of percutaneous treatment of coronary artery disease with drug-eluting stents, CABG remains the best therapy for patients with significant left main and three-vessel coronary artery disease. The benefits of CABG are accentuated for patients with more severe and complex disease.

These important randomized trials have consistently demonstrated that surgical coronary artery revascularization is the ideal technique to reduce symptoms, myocardial infarctions, cardiac-related future hospitalizations, and death in patients with advanced coronary artery atherosclerosis. Improvements in nonsurgical therapy, both medical and percutaneous, have prompted recurring investigations into the comparative efficacy of coronary bypass surgery. Surgical treatment continues to successfully compete, largely because of simultaneous advances in surgical technique, intraoperative patient care, and postoperative management. Despite concerns raised every year that CABG will no longer be performed in the future, outcomes remain superior and as a result, volumes continue to rise. It is likely that surgical revascularization of the ischemic heart will continue to be the dominant strategy for many years to come.

CHAPTER 84 ■ MECHANICAL CIRCULATORY SUPPORT FOR CARDIAC FAILURE

SANJEEV AGGARWAL, KEITH D. AARONSON, AND FRANCIS D. PAGANI

KEY POINTS

- 1 The term “mechanical circulatory support” (MCS) refers to a broad array of cardiac support devices that are distinguished by a number of important features including the location of the pumping chamber of the device, ventricle being supported, and pumping mechanism.
- 2 Indications for MCS include bridge to recovery, bridge to transplantation, and destination therapy (permanent implantation as an alternative to transplantation).
- 3 The major types of devices utilized for bridge to recovery are temporary, extracorporeal systems that can be placed utilizing percutaneous techniques.
- 4 Devices utilized for bridge to transplantation or destination therapy are durable, long-term devices that require major operative implantation and permit patient hospital discharge with untethered “hands free” mobility.
- 5 Delay in instituting any type of MCS increases the need for biventricular support as opposed to just left ventricular support alone. As the severity of illness and organ dysfunction increases, patients are more likely to require biventricular support and have a decreased survival secondary to the greater degree of organ failure present at implant.
- 6 Patient selection is the single most crucial factor in determining outcome of patients who receive mechanical circulatory support.
- 7 Major adverse events following initiation of MCS include stroke, infection, bleeding, right heart failure, and device malfunction.
- 8 The Interagency Registry of Mechanically Assisted Circulatory Support (INTERMACS) is a National Institutes of Health–funded data registry to study outcomes for patients receiving durable, long-term implantable ventricular assist devices.
- 9 Major technologic advances in device design for both temporary and long-term durable devices have incorporated continuous flow rotary pumps with axial or centrifugal design.

- 1 The term “mechanical circulatory support” (MCS) refers to a broad array of cardiac support devices. These devices are distinguished by a number of important features including (a) the location of the pumping chamber of the device, whether located outside the body or inside the body (extracorporeal vs. intracorporeal or “implantable”) (Fig. 84.1), (b) the ventricle being supported (left ventricular assist device [LVAD] vs. right ventricular assist device [RVAD] vs. biventricular assist device [BiVAD] vs. total artificial heart [TAH]) (Fig. 84.2), and (c) the pumping mechanism (pulsatile, volume displacement device vs. continuous flow rotary device with axial or centrifugal design) (Algorithm 84.1). Generally, systems designed for short-term use have the pumping chamber located outside the body (extracorporeal or paracorporeal location), while “durable” systems intended for long-term (months to years) use have the pumping system located within the body.
- 3 tors, with a reasonable expectation that the myocardial injury is reversible and that myocardial function will recover during a short period of temporary MCS (generally days to several weeks). The short-term utilization of MCS for BTR is the most common application of MCS in the United States.¹ Examples of reversible forms of myocardial injury include acute myocardial infarction, viral myocarditis, and postcardiotomy cardiogenic shock with failure to wean from cardiopulmonary bypass (CPB) following open heart cardiac procedures due to ischemic myocardial stunning or inadequate valvular repair or replacement. Several types of devices can provide temporary MCS in these circumstances and include an intra-aortic balloon pump (IABP), extracorporeal ventricular assist device (VAD), and extracorporeal membrane oxygenation (ECMO, or preferably referred to as extracorporeal life support [ECLS], which provides both cardiac and pulmonary support). Generally, temporary MCS devices are placed percutaneously to facilitate rapid initiation of cardiac support and, alternatively, ease of removal when cardiac function returns. Some types of extracorporeal VAD systems require major operative procedures with sternotomy for access and placement and are more frequently utilized at the time of postcardiotomy failure to wean while the heart is exposed through sternotomy from the prior open heart procedure.

INDICATIONS FOR MECHANICAL CIRCULATORY SUPPORT AND DEVICE SELECTION

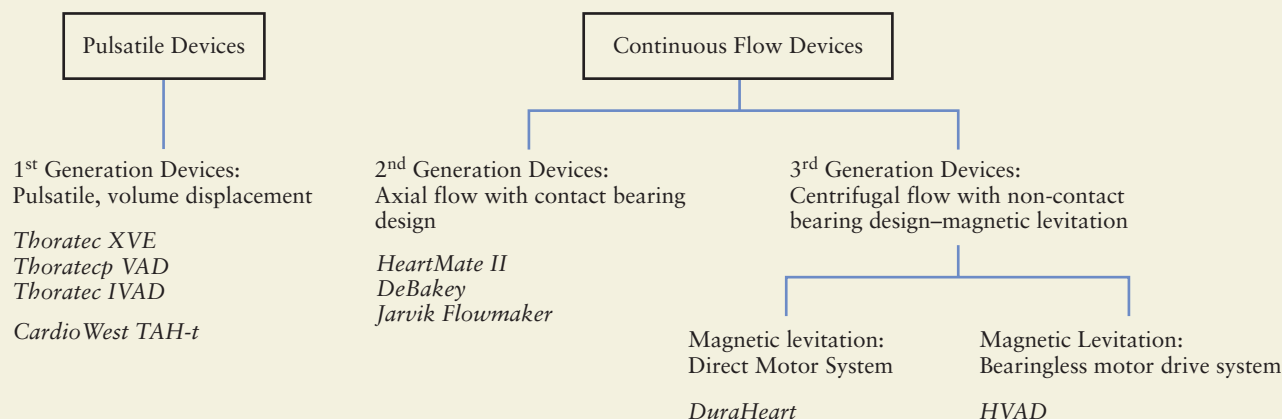

- The spectrum of MCS therapy is complex due to multiple indications for use and availability of numerous types of MCS devices. Currently, there are three accepted indications for MCS. These treatment paradigms have been developed based on regulatory oversight by the U.S. Food and Drug Administration (FDA) and historical use of the therapy.
- 2 “Bridge to recovery” (BTR) refers to the use of MCS in patients who are presenting with acute cardiogenic shock or decompensated heart failure, despite the use of optimal medical therapy including intravenous inotropes and/or vasoconstrictors.
 - 4 The second indication for MCS applies to patients presenting with cardiogenic shock or decompensated advanced heart failure refractory to optimal medical management in whom myocardial function is unlikely to recover and the patients are considered candidates for heart transplantation (long-standing ischemic, valvular, or idiopathic cardiomyopathy; severe acute myocardial infarction or myocarditis). Durable MCS devices designed for long-term use that are implantable and permit untethered patient mobility and discharge from the hospital are

Classification of MCS Devices by Intended Duration of Support and Pump Design

Temporary Mechanical Circulatory Support Devices

Long-term Durable Mechanical Circulatory Support Devices

ALGORITHM 84.1

ALGORITHM 84.1. Classification of mechanical circulatory support devices by the pumping mechanism (pulsatile, volume displacement, or continuous flow rotary pumps) (Abiomed BVS 5000, Abiomed AB 5000, Impella 2.5 LP, Impella 5.0 LP, Abiomed Corporation, Danvers, MA; HeartMate XVE, Thoratec pVAD, Thoratec IVAD, HeartMate II, Thoratec Corporation, Pleasanton, CA; CardioWest TAH, Syncardia Systems, Tucson, AZ; Tandem Heart pVAD, Cardiac Assist Corporation, Pittsburgh, PA; CentriMag VAD, Levitronix LLC, Waltham, MA; HeartAssist 5 [DeBakey LVAD], Micromed Cardiovascular Corporation, Houston, TX; Jarvik LVAD, Jarvik Heart Corporation, New York, NY; DuraHeart LVAD, Terumo Heart Corporation, Ann Arbor, MI; HVAD LVAD, HeartWare Corporation, Miami, FL).

appropriate devices for a “bridge to transplantation” (BTT) indication. Implantable pumps require a major operative procedure for placement, including CPB in many instances, and are ideally placed in patients with significant symptoms of heart failure who are dependent on intravenous inotropes but with stable hemodynamics and end-organ function.

The third indication for MCS applies to patients with chronic refractory symptoms of advanced heart failure due to irreversible forms of either nonischemic or ischemic cardiomyopathy and who are not eligible for heart transplantation. The application of MCS in this setting is termed “destination therapy” (DT). Implantable devices with proven long-term reliability permitting untethered “hands free” patient mobility at home are appropriate devices in this clinical situation.² Again, these implantable pumps require a major operative procedure for placement and are ideally placed in patients with significant symptoms of heart failure but with stable hemodynamics. The survival, functional, and quality-of-life benefit of MCS for DT for the treatment of chronic advanced heart failure was established in a prospective randomized trial known as REMATCH (Randomized Evaluation of Mechanical Assistance in the Treatment of Congestive Heart Failure).² REMATCH evaluated the use of an implantable LVAD compared to optimal medical therapy for refractory chronic

advanced heart failure. LVAD therapy halved (relative risk, 0.52; 95% confidence limit, 0.34–0.78) the mortality seen in the control population treated with optimal medical therapy, which was 92% at 2 years. Despite serious adverse events attributable to MCS from infection, bleeding, and device malfunction, LVAD recipients had an improved survival rate and experienced a superior quality of life than the medical therapy group. Currently, patients evaluated for DT must meet specific criteria that include (a) New York Heart Association (NYHA) class IV or stage D heart failure symptoms, (b) a left ventricular ejection fraction of less than 25%, (c) a peak exercise oxygen consumption of less than 14 mL/kg per minute, and (d) significant functional limitations despite the use of maximally tolerated doses of drugs outlined in the recent guidelines for heart failure treatment for at least 60 of 90 days.

The intended use and indication for MCS has significant influences on the appropriate device selection and use. The decision to initiate MCS must include an analysis of the intended use, clinical setting, patient variables and condition, type of MCS devices available, and FDA approval and guidelines for use of the device. The paradigms of BTR, BTT, and DT have become integrated into the way that MCS is currently delivered by clinicians, regulatory agencies, and insurance payers. These paradigms do not consistently describe all clinical situations and

realities of patient care, and it is likely that changes in indications for MCS will continue to evolve in the future.³

TIMING OF MECHANICAL CIRCULATORY SUPPORT INTERVENTION

Timing the initiation of MCS is crucial to patient outcome. There are no absolute hemodynamic criteria to meet in order to initiate MCS for any indication. Generally, patients presenting with acute forms of myocardial injury have recognizable changes in hemodynamics. A cardiac index less than 1.8 to 2.2 L/min per m², systolic blood pressure less than 90 mm Hg, pulmonary capillary wedge pressure greater than 20 mm Hg, right atrial pressure greater than 18 to 20 mm Hg, and evidence of poor tissue perfusion, reflected by oliguria, rising creatinine and liver transaminases, mental status changes, or cool extremities, despite the use of optimal medical therapy, are general guidelines to initiate MCS. Patient history and overall clinical setting also need to be considered in the decision. When patients reach this degree of hemodynamic compromise, the risk of death is substantial and is in excess of 50% at 30 days despite the availability of optimal medical therapy, invasive circulatory monitoring, thrombolysis, and IABP support.^{4,5}

More subtle indications to initiate MCS may be present, particularly in the group of patients suffering from chronic advanced heart failure who are being evaluated for BTT or DT. These indications include resting tachycardia, progressive organ dysfunction, persistent significant symptoms of heart failure resulting in limited functional capacity, and poor quality of life despite optimal medical management with or without inotrope therapy. Deterioration in end-organ function or progressive decline in functional performance may occur in the absence of a significant change in hemodynamic parameters (chronic adaptation to low cardiac output). In addition, patients who do not tolerate optimal medical management for advanced heart failure and experience renal insufficiency or hypotension in the setting of optimal dosages of angiotensin-converting enzyme (ACE) inhibitors or beta-blockers may need evaluation for MCS therapy. Patients who do not tolerate inotrope therapy as a result of refractory ventricular arrhythmias or have life-threatening

coronary anatomy and unstable angina not amenable to revascularization, and are at risk of imminent death (hours, days, or weeks), may be considered for MCS without necessarily meeting hemodynamic criteria.

In the setting of postcardiotomy shock, data from the Abiomed BVS 5000 registry demonstrated that delay in initiating temporary MCS for more than 6 hours after the initial weaning from CPB was associated with a significant decrease in survival, 44% versus 14%.⁶⁻⁸ Delay in instituting any type of MCS increases the need for biventricular support as opposed to just LV support alone. As the severity of illness and organ dysfunction increases, patients are more likely to require biventricular support and have a decreased survival secondary to the greater degree of organ failure present at implant.⁹⁻¹⁴ An episode of cardiac arrest prior to the initiation of MCS significantly reduces survival, from 47% to 7%.^{6,7}

PATIENT SELECTION AND INFLUENCE OF COMORBIDITIES ON OUTCOMES

- 6 Patient selection is a crucial factor in determining outcome of patients who receive MCS. Generally, patients should be excluded for consideration for MCS in situations where cardiac recovery is unlikely and the options of heart transplantation and DT are not feasible. Under these circumstances, MCS support is generally considered futile. More general contraindications for initiating MCS include irreversible renal, hepatic, or respiratory failure; sepsis; or a significant cognitive deficit.

Renal Function

Renal dysfunction has consistently been one of the greatest risks for morbidity and mortality with the use of MCS.¹⁵⁻²⁰ Renal dysfunction is often secondary to decreased perfusion of the kidney in cardiogenic shock, but may also be due to nephrotoxic effects of drugs utilized for heart failure therapy. In patients with shock or advanced heart failure, it is difficult to assess the reversibility of renal dysfunction. Acute onset of renal failure requiring renal replacement therapy is not necessarily a contraindication to initiate short-term MCS, but may be more of an obstacle to successful long-term support with implantable devices for BTT and in particular DT. In the setting of cardiogenic shock with acute renal failure, establishing normal hemodynamics with MCS may resolve the renal failure in a relatively short period of time. Thus, the degree and duration of cardiogenic shock along with the patient's baseline renal function must be considered in estimating the probability of recovery of renal function.

Pulmonary Function

Heart failure may be associated with a restrictive pattern on pulmonary function testing. However, this often improves with removal of interstitial fluid and intrathoracic effusions after placement of an MCS device and resolution of lung congestion. Patients with a long history of smoking or a history of other intrinsic lung disease with significant abnormalities on pulmonary function testing (i.e., <50% of normal in forced vital capacity [FVC], forced expiratory volume in 1 second [FEV₁], or diffusing lung capacity for carbon dioxide [DLCO]) warrant high-resolution computerized tomography (CT). Patients with low oxygen saturation (<92%) on room air also warrant evaluation with echocardiography to rule out a right-to-left shunt from an atrial septal defect or patent foramen ovale (PFO) and, if negative, a spiral CT or nuclear scan to rule out thromboembolic disease. Patients with severe pulmonary disease may have an elevated pulmonary vascular resistance that is fixed (not responsive to pulmonary artery vasodilators). High fixed pulmonary vascular resistance (generally >6 Wood units) represents

a contraindication to heart transplantation and thus BTT indication. Perioperative hypoxia as a result of significant underlying lung disease may also contribute to pulmonary vasoconstriction leading to right ventricular (RV) failure following institution of LVAD support. Moderate elevations in pulmonary vascular resistance can be encountered in patients with cardiogenic shock and does not preclude successful use of MCS if reversibility or lowering of the pulmonary vascular resistance is achieved with inotropes or pulmonary vasodilators.

Liver Function

Previous studies have reported that total bilirubin levels and hepatic cellular enzymes more than three times normal are independent risk factors for adverse outcomes.^{15–18} The etiology of the hyperbilirubinemia may be multifactorial, including “cardiac congestion” or cirrhosis, cholestatic jaundice, or a combination of etiologies. Abnormal liver function is often associated with abnormal coagulation factors, as well as low serum albumin. Attempts should be made to normalize all measurements of liver function and their cause(s) preoperatively. The presence of portal hypertension with liver cirrhosis is a contraindication to initiating MCS support. A history of significant alcohol use should be reviewed in all potential candidates for MCS therapy, especially those with abnormal liver function. Patients should also be tested for previous infection with hepatitis A, B, or C or other viruses. Ultrasound visualization of the liver is a good screen for patients with significant hepatomegaly to rule out infiltrative disease, mass, or other pathology that may warrant biopsy. Improvement in hepatic congestion and recovery of synthetic functions of the liver can occur with institution of MCS.

Right Ventricular Failure

Patients with advanced heart failure frequently have coexisting RV failure. RV failure may be one of the most prominent causes of mortality or morbidity following initiation of MCS.^{10–14,21–23} RV failure in most patients is due to LV failure. Patients with a nonischemic etiology often present with significant RV failure and may have a three- to fourfold increased risk of requiring both LV and RV support. Patients who require BiVAD support have significantly higher preoperative creatinine and total bilirubin levels and a greater need for mechanical ventilation before MCS device insertion as compared to patients requiring LVAD support only. The institution of BiVAD support adversely influences survival for both short-term and long-term MCS devices as a consequence of worse preoperative organ function.^{10–14,21–23} RV failure is a prominent factor leading to renal dysfunction after LVAD implantation, as right atrial pressures greater than 20 mm Hg lead to changes in glomerular filtration from cortical to medullary nephrons, with secondary reduction in urine output and resistance to diuretic therapy.²⁴ Preoperative optimization of RV function with a goal right atrial pressure ideally less than 15 mm Hg is important for reducing the need for postoperative RV support. The higher the left atrial or wedge pressure at the time of device implantation, the greater is the benefit to the RV and pulmonary artery pressure when the LV is totally unloaded and left atrial pressure falls. However, the recovery of the right ventricle may lag for several days as total decompression of the left ventricle allows a significant shift of the interventricular septum toward the left ventricle, with further distention and dysfunction of the right ventricle.^{25–27}

Coagulation Parameters

Coagulopathy is a significant risk factor and a common abnormality noted in patients with refractory heart failure. An abnormal international normalized ratio (INR) in the absence of warfarin use is of added concern, as it may reflect chronically high

right atrial pressures, leading to hepatic congestion and, ultimately, to hepatic fibrosis and cirrhosis. Prolonged abnormal INR and low platelet count combined with use of anticoagulation or antiplatelet therapy are associated with significant perioperative bleeding, requiring multiple transfusions, leading to increased pulmonary vascular resistance, RV failure, decline in renal function, hemodynamic instability, and multiple organ failure.²⁸ In addition, patients with severe heart failure commonly have a nutritional basis for abnormal coagulation due to depletion of several specific coagulation factors, such as factor VII. The minimum preoperative screen for coagulation abnormalities should include prothrombin time (PT), partial thromboplastin time (PTT), INR, platelet count, platelet aggregation studies, and possibly a heparin-induced thrombocytopenia (HIT) assay. The presence or development of HIT is associated with a high risk of bleeding as well as thrombosis of MCS devices.²⁹

Nutrition

Nutrition is an important contributor to overall outcome with MCS. A low serum albumin (<3.3 mg/dL) was the prominent risk factor for mortality and was associated with a relative increase in risk of 6.6-fold in the study by Lietz et al.,^{30,31} who evaluated outcomes with LVAD therapy for DT. Significant nutritional deficiency is often associated with poor wound healing and an increased risk of infection and impaired T-lymphocyte cell function, as manifest by cutaneous skin test anergy. Body habitus is a marker of nutrition and an important consideration in patient selection and is reliably defined by body mass index (BMI). Patients whose BMI is either less than 22 or greater than 36 are at risk for perioperative complications, but outcomes are more adversely impacted by cachexia than obesity.^{32–34} Cachexia is often due to poor appetite due to elevated tumor necrosis factor (TNF) and other cytokines, limitations in exertion and work of breathing, and early satiety in those with significant hepatomegaly.³⁵ Cessation of calorie intake for as little as 24 hours may be associated with a 50% reduction in production of critical proteins needed for wound repair. Delay in instituting MCS therapy may be warranted for several weeks when feasible to allow improvement in nutritional status, either by ingestion of various oral nutritional supplements or enteral feedings using a small feeding tube, preferentially with nocturnal feeding in those unable to consume adequate calories during the day. Early, aggressive caloric supplementation in the postoperative period is also critical to preventing or reversing malnutrition.

OTHER IMPORTANT MEDICAL CONSIDERATIONS IN INSTITUTING MECHANICAL CIRCULATORY SUPPORT

Valvular Heart Disease

Abnormalities of the cardiac valves have important adverse consequences in patients being considered for MCS and may require repair or replacement in order to initiate successful MCS or achieve weaning from support. Mild to moderate aortic stenosis in the absence of insufficiency is not a contraindication to placement of a VAD. Severe aortic stenosis should be corrected prior to placement of a VAD, preferably with a bioprosthetic valve, to facilitate future weaning or optimize native heart function in the event of device failure. The presence of even mild to moderate aortic insufficiency can have a significant impact on the effectiveness of MCS therapy. In cases where LV assistance is initiated with left atrial to aortic cannulation, aortic insufficiency will result in LV distention in the presence of significant LV dysfunction. LV distention adversely affects subendocardial

blood flow and can prevent weaning from MCS. In cases where MCS support is initiated with devices that require LV apical to aortic cannulation, reductions in LV pressure elicited by MCS increase the pressure gradient across the aortic valve and increase the degree of aortic insufficiency. Blood pumped into the aorta by the LVAD will flow backward across the incompetent aortic valve (aortic insufficiency), decreasing net forward flow and compromising end-organ perfusion. Mild to moderate aortic insufficiency may become more severe with initiation of MCS from an LVAD because the elevated LV end-diastolic pressure will be significantly reduced by emptying of the LV cavity by the device and the aortic root pressure will be elevated above baseline because of device flow. The presence of significant aortic insufficiency can be confirmed by echocardiography. Patients with a mechanical valve prosthesis in the aortic valve position should have the mechanical valve replaced with a bioprosthetic valve prior to institution of LV assistance. During complete unloading of the left ventricle by a VAD, the aortic valve may not open and the mechanical valve may be prone to thrombus formation.

Patients with significant mitral stenosis at the time of initiation of device support may require correction of the valvular problem before implantation of a device depending on device selection and site of cannulation. In the setting of significant mitral stenosis, LV filling is impaired. VADs that utilize apical ventriculotomy for cannula placement for ventricular drainage may experience limitations in device filling due to mitral stenosis. This problem can be circumvented by either choosing a device that can utilize left atrial drainage or by correcting the underlying valvular pathology (mitral valve repair or replacement with a bioprosthetic valve). Mitral regurgitation does not have an impact on the filling of a VAD. In situations where weaning from MCS may be feasible, correction of the mitral pathology, either stenosis or regurgitation, is necessary in order to optimize ventricular function.

Adequate RV function is extremely important to maintain LVAD flow in the early postoperative period. Severe tricuspid regurgitation can significantly impair the forward flow of blood from the right ventricle, particularly in situations of high pulmonary vascular resistance. Severe tricuspid regurgitation contributes to elevated central venous pressure, hepatic congestion, and renal dysfunction. Severe tricuspid regurgitation may be present preoperatively in the setting of volume overload and biventricular failure or may develop following institution of LVAD support as a consequence of RV dilation from leftward shift of the interventricular septum.^{25–27} If severe tricuspid regurgitation is present during the initiation of LVAD support, tricuspid valve repair should be performed to improve RV performance.

Coronary Artery Disease

Patients with significant obstructive coronary artery disease or patients with postcardiotomy shock following failed coronary bypass operations may experience angina during MCS. Generally, coronary artery disease does not have adverse hemodynamic consequences during the period of MCS. However, the presence of obstructive coronary disease with ongoing ischemia may limit the degree of myocardial recovery and impact the ability to wean from temporary MCS.

Perioperative ischemia of the right ventricle may be of hemodynamic significance during institution of LVAD support. RV ischemia causing myocardial stunning or infarction that occurs during or soon after implantation of an LVAD can elicit RV failure, resulting in decreased flow to the LVAD. In patients who have had coronary bypass surgery and are candidates for MCS, patent bypass grafts, particularly to the right coronary artery or left anterior descending coronary artery, should be preserved in order to reduce the risk of perioperative RV failure and arrhythmias. In selected situations it may be important to perform a coronary artery bypass to the right

coronary artery or left anterior descending coronary artery systems to optimize RV function in the perioperative period if significant obstructive coronary lesions amenable to bypass are present in the distribution of these arteries.

Arrhythmias

Atrial and ventricular arrhythmias are common in patients with cardiogenic shock and underlying ischemic or idiopathic cardiomyopathies. These arrhythmias generally persist in the immediate postoperative period and subsequently resolve with time as the hemodynamic condition of the patient improves and inotrope therapy is weaned. Some patients will have persistent arrhythmias due to their underlying pathology (i.e., giant cell myocarditis). Severe ventricular arrhythmias have traditionally been thought to be a contraindication to uni-ventricular support. However, recent experience has revealed that the hemodynamic consequences in patients in whom these arrhythmias develop in the late postoperative period are generally not life-threatening.^{36–38} In the absence of pulmonary hypertension and elevated pulmonary vascular resistance in the postoperative period, patients maintain adequate LVAD flows during ventricular fibrillation. This situation is analogous to a Fontan (systemic vein to pulmonary artery) circulation. In the early perioperative period, some patients with refractory ventricular arrhythmias may require biventricular support until the pulmonary vasculature resistance drops and a Fontan circulation is tolerated. The addition of RV support for hemodynamic compromise due to refractory ventricular arrhythmia is unusual. In situations where weaning from MCS is feasible or planned, elimination of the ventricular arrhythmias with antiarrhythmic therapy is essential.

Intracardiac Shunts

Intracardiac shunts, such as a patent foramen ovale or atrial septal defect, should be closed at the time of implantation of an LVAD to prevent right-to-left shunting. These anomalies should be identified prior to surgery using transesophageal echocardiogram.³⁹ During the initiation of LV assistance, left atrial pressure is reduced compared to right atrial pressure. This gradient causes shunting of deoxygenated blood from the right atrium into the left, resulting in significant systemic hypoxemia.

PATIENT OUTCOMES AND MAJOR ADVERSE EVENTS FOLLOWING INITIATION OF MECHANICAL CIRCULATORY SUPPORT

Survival, as well as the occurrence of significant adverse events following the initiation of MCS therapy, is dependent on the clinical presentation, indication for MCS therapy, and type of device utilized. Generally, adverse outcomes are associated with a greater acuity and severity of illness and are generally higher when temporary MCS devices are utilized in the emergent situation. Bleeding, stroke and thromboembolism, infection, and RV failure are the most frequent complications that occur in the early postoperative period following initiation of MCS. Major adverse events most common in the late postoperative period include infection and device failure.

Bleeding

Bleeding is a frequent, early complication in patients supported by MCS and generally requires reoperation in the early postoperative period. Risk factors for bleeding include preoperative

hepatic congestion and failure, poor preoperative nutritional status, prolonged CPB times, extensive surgical dissection, reoperative surgery, multiple cannulation sites, decreased platelet function, and induction of fibrinolysis as a result of contact with biomaterial surfaces during CPB and MCS devices. In the early experience of MCS, about 50% of patients required reoperation for bleeding. The rate still remains significant even with the incorporation of new device technology.

Right Ventricular Failure (see Right Ventricular Failure under Patient Selection and Influence of Comorbidities on Outcomes)

RV failure occurs in approximately 7% to 20% of patients supported by LV assistance alone. The etiology of RV failure is multifactorial and includes pathologies within the pulmonary vascular bed and/or right ventricle. Factors contributing to RV failure include impaired RV function as a result of intraoperative air embolism, myocardial stunning as a result of poor intraoperative myocardial protection, ischemia and infarction from coronary artery disease, arrhythmias, volume loading, and alteration of RV septal geometry induced by LV unloading. Several studies have demonstrated that factors, such as elevated central venous pressure, reduced RV stroke work index, low preoperative pulmonary artery pressures, transpulmonary gradient greater than 16 mm Hg, acute decrease in pulmonary artery pressures equal to or greater than 10 mm Hg at the onset of LVAD support, degree of preoperative pulmonary edema, increased need for perioperative transfusions, increasing degree of renal and hepatic dysfunction, female gender, nonischemic etiology, and preoperative temporary MCS support, all increase the need for RV MCS following LVAD implantation.^{12–14,23,40,41} Acute unloading of the left ventricle by MCS may cause the septum to shift leftward, increasing RV volume loading and reducing its function.^{25–27} The negative consequences of this phenomenon may be offset by the reduction in pulmonary artery pressures and RV afterload caused by device-mediated LV decompression.^{25–27} Hemodynamic stability can be attained with isolated mechanical LV support in approximately 90% of patients, even in those patients with substantial RV dysfunction, if there is effective replacement of left-sided heart function and aggressive treatment of pulmonary hypertension. More recently, the improved perioperative management of elevated pulmonary vascular resistance including the use of inhaled nitric oxide, a specific, potent pulmonary vasodilator, in combination with milrinone, isoproterenol, or dobutamine has significantly reduced the need for placement of a RVAD.^{42–44} In patients with marked elevation of central venous pressure, multiorgan failure, or severe RV dysfunction with low pulmonary artery pressures, early biventricular support may be indicated.^{12–14,23}

Stroke and Thromboembolism

The occurrence of thromboembolic events following MCS is variable and depends on a number of factors including the type of device, duration of support, location and number of cannulation sites, and presence of prosthetic valves within the heart. Approximately 10% of patients receiving MCS with implantable devices will experience a thromboembolic event or stroke.^{45,46} This rate is in the range of 20% for patients on short-term extracorporeal MCS devices. Improvement in the rate of thromboembolic events has come from more aggressive antiplatelet therapy in conjunction with warfarin, improved device design, and more frequent use of LV apical as compared to left atrial cannulation. In patients supported for short durations only, anticoagulation is usually achieved with heparin and antiplatelet therapy. Longer-term support usually requires transition to warfarin and antiplatelet therapy for most, but not all, devices.

Infection

Infections can be device related (i.e., device endocarditis, percutaneous lead or cannula site infection, pocket infection [infection external to an implanted device]) or non-device related (i.e., pneumonia, urinary tract infection). The incidence of early nosocomial non-device-related or device-related infections in patients undergoing MCS is approximately 30% to 40% in many series and is related to the acuity of illness in this population of patients.^{46–54} Patients with persistent or recurrent sepsis and those patients with device-related infections tend to have a higher mortality than patients without these complications. In patients on long-term MCS, infection remains the single most significant obstacle to successful outcome. Infection was the most common cause of mortality during LVAD support seen in the REMATCH trial, with infection contributing to 41% of deaths.³ Within 3 months after implantation, the probability of infection with the device was 28%. Most of these late infections began in the percutaneous tube (driveline) tract and pocket of the device. However, clinical experience has revealed that VAD infection rates can be minimized with attention to infection control guidelines, optimal implantation techniques, meticulous wound care, and the utilization of new continuous flow rotary pump technology.^{46,55,56}

Risk factors for development of infection that are present before device insertion include preoperative infection at remote sites (not in the area of implantation), malnutrition, prolonged hospitalization, immobilization, broad-spectrum antibiotic therapy, immunosuppressive medications (i.e., steroids), mechanical ventilation, and the presence of central venous catheters. The percutaneous lead of the device can be a portal of entry for bacterial and fungal pathogens. Intracorporeal device infections can occur within the pumps themselves and on their outer surfaces, which are generally caused by biofilm-forming bacteria and fungi (e.g., *Staphylococcus* species). Device-related infections can sometimes be successfully treated with antibiotic suppression and device exchange or removal. Infections involving the preperitoneal pocket (subfascial space created for device placement) surrounding implantable VADs require more aggressive treatment, including open drainage, débridement, and rerouting of the percutaneous lead through a fresh exit site. However, patients who are device dependent and awaiting transplantation generally cannot tolerate device removal as a therapeutic option to eradicate the infection. Antibiotic suppression and transplantation remain the only chance for cure of device-related infections in these instances. These infections do not generally preclude heart transplantation, and transplant outcomes and survival are generally not significantly affected in this situation.^{50,56}

Device Malfunction

As with any mechanical device, malfunction is an anticipated occurrence. The types and severity of device malfunctions vary with each of the devices. Many devices have built-in backup systems that, in the event of catastrophic device failure, provide support to the patient. Also, most patients supported by a VAD have enough residual LV function to help sustain them until corrective measures can be taken. New technology incorporating continuous flow rotary pump design presents new challenges to device malfunction. These devices do not contain valves to direct the flow of blood, and stoppage of the pump is associated with significant regurgitation of blood through the device, resulting in significant LV distention. This phenomenon is similar to the development of acute aortic insufficiency. Fortunately, the reported frequency of this event is low.⁴⁶ Device malfunctions in total artificial hearts are more problematic as there is no native heart to provide hemodynamic support in the event of a total device failure. Stringent quality control measures in fabrication and testing and very low mechanical failure rates are therefore even more essential with total artificial hearts.

Interagency Registry for Mechanically Assisted Circulatory Support

- 8 The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database, funded by the U.S. National Heart, Lung and Blood Institute (NHLBI), is a registry for patients who receive implantable or “durable” VAD devices that are approved by the FDA.^{57–60} The INTERMACS registry represents one of the largest available data repositories for the study of VAD outcomes intended for BTT or DT. The most recent published data analysis of MCS outcomes for VAD therapy reviews the nearly 3 years of data entry into the

registry and largely represents outcomes from patients undergoing implantation with the first generation of pulsatile, volume displacement technology, such as the HeartMate XVE (Thoratec Corporation, Pleasanton, California), Thoratec pVAD (Thoratec Corporation, Pleasanton, California), Thoratec iVAD (Thoratec Corporation, Pleasanton, California), and Novacor LVAD (World Heart Corporation, Oakland, California), and second-generation technology with continuous flow rotary pumps.^{57–60} Survival with LVAD support alone at 2 years was approximately 50% and was significantly worse for those patients requiring BiVAD support or support with a TAH^{57–60} (Figs. 84.3 and 84.4 and Table 84.1). Patients undergoing implantation of an MCS device in the

TABLE 84.1

DESCRIPTION OF INTERMACS PROFILES DESCRIBING DEGREE OF HEART FAILURE SYMPTOMS AND HEMODYNAMIC STATUS AT THE TIME OF MECHANICAL CIRCULATORY SUPPORT IMPLANTATION AND INCLUDING THE TIME FRAME FOR INTERVENTION⁵⁷

■ INTERMACS PROFILE DESCRIPTIONS	■ TIME FRAME FOR INTERVENTION
<p>Profile 1: Critical cardiogenic shock Patients with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion, often confirmed by worsening acidosis and/or lactate levels. “<i>Crash or burn.</i>”</p>	Definitive intervention needed within hours.
<p>Profile 2: Progressive decline Patient with declining function despite intravenous inotropic support, may be manifest by worsening renal function, nutritional deprivation, inability to restore volume balance. “<i>Sliding on inotropes.</i>” Also describes declining status in patients unable to tolerate inotropic therapy.</p>	Definitive intervention needed within few days.
<p>Profile 3: Stable but inotrope dependent Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support (or a temporary circulatory support device or both), but demonstrating repeated failure to wean from support due to recurrent symptomatic hypotension or renal dysfunction. “<i>Dependent stability.</i>”</p>	Definitive intervention elective over a period of weeks to few months.
<p>Profile 4: Resting symptoms Patient can be stabilized close to normal volume status but experience daily symptoms of congestion at rest or during ADL. Doses of diuretics generally fluctuate at very high levels. More intensive management and surveillance strategies should be considered, which may in some cases reveal poor compliance that would compromise outcomes with any therapy. Some patients may shuffle between 4 and 5.</p>	Definitive intervention elective over period of weeks to few months.
<p>Profile 5: Exertion intolerant Comfortable at rest and with ADL but unable to engage in any other activity, living predominantly within the house. Patients are comfortable at rest without congestive symptoms, but may have underlying refractory elevated volume status, often with renal dysfunction. If underlying nutritional status and organ function are marginal, patient may be more at risk with INTERMACS 4, and require definitive intervention.</p>	Variable urgency, depends upon maintenance of nutrition, organ function, and activity.
<p>Profile 6: Exertion limited Patient without evidence of fluid overload is comfortable at rest, and with ADLs and minor activities outside the home but fatigues after the first few minutes of any meaningful activity. Attribution to cardiac limitation requires careful measurement of peak oxygen consumption, in some cases with hemodynamic monitoring to confirm severity of cardiac impairment. “<i>Walking wounded.</i>”</p>	Variable, depends upon maintenance of nutrition, organ function, and activity level.
<p>Profile 7: Advanced NYHA III A placeholder for more precise specification in future, this level included patients who are without current or recent episodes of unstable fluid balance, living comfortably with meaningful activity limited to mild physical exertion.</p>	Transplantation or circulatory support may not currently be indicated.
<p>Modifiers for Profiles</p> <p>TCS: Temporary Circulatory Support can modify only patients in hospital (other devices would be INTERMACS devices). Includes IABP, ECMO, TandemHeart, Levitronix, BVS 5000 or AB5000, Impella</p> <p>A-Arrhythmia: can modify any profile. Recurrent ventricular tachyarrhythmias that have recently contributed substantially to clinical compromise. This includes frequent ICD shock or requirement for external defibrillator, usually more than twice weekly.</p> <p>FF: Frequent Flyer can modify only outpatients, designating a patient requiring frequent emergency visits or hospitalizations for diuretics, ultrafiltration, or temporary intravenous vasoactive therapy.</p>	<p>Possible Profiles to Modify</p> <p>1, 2, 3 in hospital.</p> <p>Any profile.</p> <p>3 if at home, 4, 5, 6. A frequent flyer would rarely be profile 7.</p>
<p>INTERMACS, Interagency Registry for Mechanically Assisted Circulatory Support. From Stevenson LW, Pagani FD, Young JB, et al. INTERMACS profiles of advanced heart failure: the current picture. <i>J Heart Lung Transplant</i> 2009;28:535–541.</p>	

presence of critical cardiogenic shock (i.e., INTERMACS level 1) had worse outcomes compared to device implantation in patients with more stable forms of advanced heart failure (INTERMACS levels 2 through 7)^{57–60} (Figs. 84.3 and 84.4 and Table 84.1). These observations highlight the importance of proper patient selection and timing of initiation of MCS therapy on outcomes. Patients with significant organ dysfunction

at the time of MCS device implant, accompanied by a greater degree of hemodynamic compromise, have a significantly higher risk of requiring BiVAD support, higher risk of major adverse events, and significantly higher risk of death during VAD support.

Since May 2008, following FDA approval of the HeartMate II LVAD, an increasing number of patients entered into

the INTERMACS registry have received MCS device support with the new generation of continuous flow rotary pump technology. Subsequent reports from the INTERMACS registry will highlight outcomes from new continuous flow rotary pump technology and offer unique insight with comparison to older technology for BTT indications.

WEANING PATIENTS FROM MECHANICAL CIRCULATORY SUPPORT

Weaning from Short-term Mechanical Circulatory Support

A number of factors are considered when weaning patients from MCS. The first consideration is an assessment of pathologic abnormalities of the heart, such as valvular disease or severe coronary disease, that have not been addressed and corrected. If the underlying pathology that has caused the patient to require MCS is not corrected, then the chances of weaning from MCS will be negligible. Cardiac tamponade must also be excluded. Bleeding is a major early complication of MCS and reoperation for cardiac tamponade and bleeding is frequent. Transesophageal echocardiogram may not reliably identify cardiac tamponade in the early postoperative period. Thus, a high index of suspicion and low threshold for reoperation is critical to rule out tamponade. Volume status, preload and afterload, cardiac rhythm, and degree of inotropic support should be optimized for weaning. Noncardiac causes can contribute to failure to wean from MCS. Pulmonary edema, elevated pulmonary vascular resistance, acute respiratory distress syndrome (ARDS), and pneumonia may hinder RV function.

Once a patient's status has been optimized, weaning from MCS with the use of transesophageal echocardiogram is ideal. As device flows are reduced, transesophageal echocardiogram provides information on ventricular filling and performance and valve function. If patients can maintain satisfactory hemodynamics with reduction of pump flow, they can be considered for weaning. In the setting of biventricular support, it is important that device flows on the right side be reduced prior to turning down left-sided device flows to prevent pulmonary edema in the event of inadequate LV function. As device flows are reduced, native heart function will begin to support the circulation. If hemodynamics are unsatisfactory during the weaning trial, the patient will require continued support and subsequent weaning trials. When weaning from MCS is not possible, patients should be evaluated for heart transplantation and bridged to a long-term MCS device if feasible.

Weaning from Long-term Mechanical Circulatory Support

Anecdotal observations from the cumulative experience with long-term MCS for BTT and recent small clinical studies have demonstrated that long-term MCS, associated with sustained mechanical unloading of the left ventricle, can improve myocardial function in those patients thought to have irreversible, dilated, end-stage nonischemic cardiomyopathies.⁶¹⁻⁶³ Several studies have demonstrated that long-term MCS can restore ventricular geometry; improve myocyte function, orientation, and size; reduce myocyte apoptosis; reduce myocardial cytokine gene and protein expression; reverse abnormal neuro-hormonal patterns associated with advanced heart failure; and improve myocardial mitochondrial function.⁶¹⁻⁶³ These observations have led clinicians to consider MCS alone, or in conjunction with other future possible therapies (novel medications, gene therapy, myocyte or stem cell implantation), as a potential modality to reverse end-stage cardiomyopathy.

FIGURE 84.5. Intra-aortic balloon pump. A: Catheter-mounted balloon is positioned within the thoracic aorta through a percutaneous insertion in the groin. B: Console for the intra-aortic balloon pump.

Whether these observations hold under future rigorous experimental scrutiny remains unknown at this time.

MECHANICAL CIRCULATORY SUPPORT DEVICES

There are two broad categories of MCS devices separated by the intent of the duration to support patients and their ability to discharge patients safely to home.

Devices Intended for Short-term Mechanical Circulatory Support

Intra-aortic Balloon Pump. The most frequent MCS device in utilization today is the IABP (Figs. 84.5 and 84.6).

FIGURE 84.6. Aortic pressure tracing during intra-aortic balloon pump support. Balloon counterpulsation is occurring after every other heartbeat (1:2 counterpulsation). With correct timing, balloon inflation (IP) begins immediately after aortic valve closure, signaled by the diastolic notch (DN). Compared with unassisted ejection, the pump augments diastolic blood flow by increasing peak aortic pressure during diastole (PDP). Balloon deflation before systole decreases ventricular afterload, with lower aortic end-diastolic pressure (balloon aortic end-diastolic pressure [BAEDP] vs. patient aortic end-diastolic pressure [PAEDP]) and lower peak systolic pressure (assisted peak systolic pressure [APSP] vs. peak systolic pressure [PSP]). (Courtesy of St. Jude Medical, Inc., Cardiac Assist Division, Minneapolis, MN.)

The first clinical use of the IABP was reported by Kantrowitz et al. in 1968.⁶⁴ The IABP can be inserted percutaneously and is positioned within the descending thoracic aorta. The IABP may augment cardiac output by 10% to 25% depending on the balloon size, patient size, degree of aortic compliance, cardiac rhythm, blood pressure, and IABP settings and timing. The concept for the IABP was based on the observation that the area under the arterial pressure trace (time-tension index) was an indirect estimation of the heart's oxygen consumption. Deflation just before ejection effectively decreases afterload and thus the work of the heart during systole. Balloon inflation during diastole increases diastolic pressure and hence coronary perfusion. Cardiac output improves from enhanced myocardial contractility as a result of increased coronary blood flow and reduced afterload and preload. Patients with ischemic cardiomyopathy have the greatest potential in increase in cardiac output from improved cardiac contractility resulting from enhanced coronary perfusion during diastole. Complications from use of the IABP include leg ischemia, balloon rupture, thrombosis within the balloon, sepsis, infection at the insertion site, bleeding, false aneurysm formation, lymph fistula, femoral neuropathy, vessel perforation with hemorrhage, and aortic dissection from catheter passage below the intima. Depending on the extent of peripheral vascular disease, balloon position can occlude major branches of the aorta and elicit ischemia of the tissues supplied by these vessels. Female gender, peripheral vascular disease, diabetes, smoking, advanced age, obesity, and cardiogenic shock are risk factors for the development of leg ischemia. The IABP has several disadvantages. In the best of circumstances, cardiac output is augmented by 25% as compared to LVADs, which can augment cardiac output by three to five times baseline flows. Mobilization and ambulation of the patient is limited while the IABP is being utilized.

Extracorporeal Life Support. ECLS, traditionally referred to as ECMO, is a temporary form of MCS that provides circulatory assistance as well as oxygenation and carbon dioxide removal from blood.^{65–67} The ECLS circuit is similar in concept to cardiopulmonary bypass routinely used in the operating room for cardiac procedures. However, with ECLS, safe application for extended periods of time (days) has required certain modifications, particularly the inclusion of membrane or hollow-fiber oxygenators. The first successful use of prolonged ECLS was reported by Hill et al. in 1972.⁶⁸ Subsequently, ECLS has been used in an increasing number of indications including neonatal, pediatric, and adult respiratory support; neonatal, pediatric, and adult postcardiotomy support; and as a bridge to a LVAD or heart and lung transplantation.

ECLS supports the circulation by unloading the right ventricle and draining blood from the venous circulation, oxygenating it, and returning it to the arterial circulation. ECLS does not unload the left ventricle, although LV preload is reduced by decreasing pulmonary venous return. In patients with severe LV dysfunction, the use of an IABP helps reduce LV afterload during systole and improves myocardial contractility. The use of the IABP and inotrope therapy can maintain sufficient cardiac contractility to prevent stasis within the ventricle where clot formation is possible.⁶⁹ If LV function is so severely reduced that there is no ejection, an atrial septostomy can be performed to vent pulmonary venous return. Alternatively, a left-sided vent can be connected to the venous line to relieve LV distention. It is important during ECLS support to maintain some degree of pulmonary blood flow to prevent thrombosis. Additionally, it is important to continue ventilation of the lungs to maintain the oxygen saturation of the blood ejected from the left ventricle above 90%. Poorly oxygenated blood ejected from the left ventricle will perfuse the coronary arteries and add hypoxic damage to the already injured heart. Venovenous ECLS, unlike venoarterial ECLS, maintains flow through the heart. Venoarterial ECLS is used primarily for cardiac or cardiorespiratory support, while venovenous ECLS is used for pulmonary support.

Current ECLS circuits are typically composed of a centrifugal pump with either a hollow fiber or membrane oxygenator, an oxygen blender, a pump console, a heat exchanger, and a pump cart. A roller pump is used by some centers. Cannulation for ECLS is extremely variable and depends on the clinical situation and whether venoarterial or venovenous circuit is desired. Percutaneous cannulation of the femoral vein and artery can be performed in emergent situations where institution of MCS is needed within minutes (acute cardiac and/or respiratory arrest). In less urgent situations, cut-down on the internal jugular and carotid artery or respective femoral vessels can be performed. In cases of postcardiotomy failure in the operating room, venous access can be obtained by insertion of the cannula in the right atrium and arterial outflow obtained by cannulation of the ascending aorta.

Numerous large clinical series have reported successful use of ECLS for cardiac and/or respiratory support in adult, pediatric, and neonatal patients. In the largest series reported to date, Bartlett et al. at the University of Michigan reported on the outcome of 1,000 patients supported with ECLS from 1980 through 1998.⁷⁰ Survival to hospital discharge was 88% for 586 cases of neonatal respiratory failure, 70% for 132 cases of respiratory failure in children, and 56% for 146 cases of respiratory failure in adult patients. Venovenous ECLS was the preferred method of respiratory support since 1988. For patients with cardiac failure, 33% of adult patients (31 cases) and 48% of pediatric patients (105 cases) survived to hospital discharge. Survival in adult patients was improved by utilizing ECLS as a bridge to longer-term implantable devices in patients who did not demonstrate early recovery of myocardial function.^{71–74} Conversely, the availability of long-term implantable devices has extended the use of ECLS in situations where recovery of myocardial function is unlikely.^{71–74}

Tandem Heart pVAD. The Tandem Heart pVAD (Cardiac Assist Technologies, Inc., Pittsburgh, Pennsylvania) is a percutaneous left atrial-to-femoral artery VAD⁷⁵ (Figs. 84.7 and 84.8). The pump is a low-speed, continuous flow, centrifugal pump. It is a dual-chamber pump composed of an upper housing and a lower housing assembly. The upper housing provides a conduit for inflow and outflow of blood. The lower housing assembly provides communication with the controller, the means for rotating the impeller of the VAD, and an anticoagulation infusion line integral to the pump to provide a hydrodynamic bearing, cooling of the bearing, and local anticoagulation. The controller is a microprocessor-based electromechanical drive and infusion system that is designed to be operated on AC current or on internal batteries.

Implantation of the device is performed percutaneously through the right femoral vein. A standard Brockenbrough catheter is inserted into the superior vena cava and the interatrial septum is punctured in the fossa ovalis using a Ross needle. The Brockenbrough catheter is then exchanged for a stiff guide wire with a distal soft wire loop identical to the device used for mitral valvuloplasty by the Inoue method. The transseptal puncture site is then dilated to 21 French with a two-stage dilator followed by insertion of a venous inflow cannula, which is sutured to the skin of the thigh. An arterial perfusion catheter of 14 French to 19 French is inserted percutaneously into the right femoral artery or two arterial perfusion catheters of 12 French into both femoral arteries.

In a randomized comparison of IABP with the Tandem Heart pVAD, Thiele et al. reported a more effective improvement in cardiac power index as well as other hemodynamic and metabolic variables with the Tandem Heart pVAD compared to the IABP. However, complications such as severe bleeding and limb ischemia were encountered more frequently after VAD support. Thirty-day mortality was similar between the groups.⁷⁵ The Tandem Heart pVAD is FDA approved for temporary MCS for cardiogenic shock in patients refractory to optimal medical therapy and IABP.

CentriMag VAD. The CentriMag VAD (Levitronix LLC, Waltham, Massachusetts) is an extracorporeal system composed

of a centrifugal blood pump, a motor, a console, a flow probe, and a circuit⁷⁶ (Fig. 84.9). The device is based on a magnetically levitated “bearingless motor” design. The rotor located within the upper pump housing is magnetically coupled to the lower motor housing to produce rotor levitation and spin, which combines the drive, the magnetic bearing, and the rotor function into a single unit. The motor generates the magnetic bearing force that levitates the rotor into the pump housing while also generating the torque necessary to produce the unidirectional flow. This device can produce flows of up to 10 L/min under normal physiologic conditions, with a priming volume of 31 mL. Single-center reports have demonstrated successful use of the CentriMag device as a BTR or bridge to long-term implantable VAD.^{76,77}

Impella Recover LP 2.5. The Impella Recover LP 2.5 (Abiomed Corporation, Danvers, Massachusetts) is a catheter-based, impeller-driven, axial flow pump with a maximal flow of 2.5 L/min from the left ventricle to the ascending aorta. The device is positioned across the aortic valve with the inlet port below the valve and outlet port above the aortic valve. The device can be implanted via a percutaneous approach.^{78,79} In a prospective randomized clinical trial comparing the Impella Recover LP 2.5 to IABP, cardiac index was significantly increased in patients with the LP 2.5 compared to patients supported with an IABP. Overall mortality at 30 days was similar in both groups.⁸⁰ The Impella is also available in a larger model, LP 5.0, that is capable of up to 5 L/min flow. The Impella LP 5.0 can be placed directly into the ascending aorta through the femoral artery or axillary artery.⁸¹

Extracorporeal Pulsatile Flow Circulatory Support Devices

Abiomed BVS 5000 and AB 5000. The Abiomed BVS 5000 (Abiomed Corporation, Danvers, Massachusetts) is an automated ventricular support device intended to provide complete temporary LV and/or RV support⁶⁻⁸ (Figs. 84.10 and 84.11). The Abiomed BVS 5000 is FDA approved for short-term MCS as a bridge to recovery in cases of cardiogenic shock due to postcardiotomy failure to wean, acute myocarditis, and myocardial infarction. Positioned externally, this pulsatile

system simulates normal physiologic mechanical cardiac function. A microprocessor-based drive console is used to supply power to a disposable, pneumatically driven two-chambered blood pump that supports one side of the heart. Left atrial blood inflow is returned to the ascending aorta and right atrial inflow is returned to the pulmonary artery in the case of biventricular support. Transthoracic cannulas are used to connect the external system to the patient. Each blood pump consists of two Angioflex polyurethane atrioventricularlike chambers. Trileaflet polyurethane valves are strategically positioned to separate (a) atrial and ventricular bladders and (b) ventricular

bladders and outflow cannulas. One or two disposable blood pumps are operated by a single BVS console, which automatically adjusts beat rate and systolic-to-diastolic ratio based on compressed air flow into and out of the external system. The blood pump is a dual-chamber device that incorporates an atrial (filling) chamber and a ventricular (pumping) chamber. Unidirectional flow is ensured by two trileaflet polyurethane valves fabricated from Angioflex, a biomaterial. The durations of pump systole and diastole are calculated automatically by the microprocessor to optimize pump filling and maintain a stroke volume of 83 mL. The console drives and adjusts left and right sides independently of each other. In addition to the traditional blood pumps and console, new blood pump designs and console, designated the AB 5000, have recently been introduced and approved by the FDA for short-term circulatory support. These blood pumps are connected to the patient in a paracorporeal configuration to enhance patient mobility (Fig. 84.11).

Implantable Devices Intended for Long-term Mechanical Circulatory Support for Out-of-hospital Use (Bridge to Transplantation and Destination Therapy Indications)

The majority of patients receiving long-term MCS have been supported by devices engineered with pulsatile, volume displacement designs that are represented by the HeartMate VE and XVE (Thoratec Corporation, Pleasanton, California), Thoratec pVAD and IVAD (Thoratec Corporation, Pleasanton, California), or Novacor (World Heart Corporation, Oakland, California).^{82–87} These first-generation devices are engineered with an internal reservoir chamber and inflow and outflow valves that permit cyclic filling and emptying of the device with pump actuation elicited by either pneumatic (Thoratec pVAD and

IVAD) or electrical (HeartMate VE and XVE and Novacor) drive systems. The inlet cannula of these devices is generally sewn to the left ventricular apex and the outflow graft sewn to the ascending aorta. Blood entering the left ventricle is diverted to the pump chamber and exits to the ascending aorta. The pump lies in a preperitoneal pocket created by surgical dissection below the diaphragm adjacent to the apex of the left ventricle. A percutaneous cable carrying the power supply to the pump, either pneumatic or electrical, is tunneled from the preperitoneal pocket to an external power source through the abdominal wall in the right upper quadrant.

Extended periods of MCS have highlighted limitations in the design of pulsatile, volume displacement pumps and include a large pump size restricting mobility, requirement for extensive surgical dissection for implant leading to bleeding and infection complications, a large body habitus of the recipient limiting options for device therapy for women, the presence of a large-diameter percutaneous lead for venting air, and audible pump operation. A critical limitation of these devices, particularly the HeartMate VE device and the subsequent later model, the HeartMate XVE, was the high incidence of reoperation for device exchange because of device malfunction.⁸⁸ Reports on the HeartMate VE and XVE have demonstrated a greater than 50% rate of device failure at 2 years. To overcome these limitations, newer device designs incorporating continuous flow rotary pump technology with an axial or centrifugal blood path represent the next generation of devices for long-term MCS therapy.⁸⁸

Implantable, Pulsatile, Volume Displacement Mechanical Circulatory Support Devices

HeartMate XVE Left Ventricular Assist Device. The HeartMate XVE is an implantable, pulsatile, volume displacement LVAD designed for long-term MCS^{82,83} (Fig. 84.12). The unique feature of this device is that its blood-contacting surfaces of the pump are textured with sintered titanium spheres on the rigid surface and integrally textured polyurethane on the movable surface to encourage the deposition of circulating cells with the formation of a biologic layer, obviating the need for anticoagulation with warfarin. The HeartMate blood pump consists of a flexible polyurethane diaphragm within a ridged outer titanium alloy housing. The inflow and outflow conduits of the HeartMate device each contain a 25-mm porcine valve within a titanium cage to ensure unidirectional blood flow. Diaphragm movement and blood ejection depend on an electric motor positioned below the diaphragm. The electric rotary motor within the titanium housing drives a cam up and down (translational movement) causing diaphragm movement. An external vent equalizes the air pressure and permits emergency pneumatic actuation in the event of electrical failure. The drive line is covered with a polyester velour that promotes tissue bonding and anchoring to the skin. The XVE LVAD is powered by two rechargeable batteries. The wearable electrical devices currently available have external backup mechanisms to continue support without the need for reoperation in case of failure of the device. The maximum pump flow is 9.6 L/min for the HeartMate XVE.

Thoratec IVAD. The Thoratec IVAD is a small implantable ventricular assist device (IVAD) based on the Thoratec pVAD⁸⁹⁻⁹³ (Figs. 84.13 and 84.14). The IVAD is a pneumatically driven pulsatile, volume displacement VAD that has a polyurethane blood pumping sac housed within a smooth-contoured, polished titanium alloy outer shell. The IVAD is controlled with the Thoratec TLC-II portable VAD driver, which is a small, briefcase-sized, battery-powered, pneumatic control unit that permits patient discharge from the hospital. A small flexible (9-mm outside diameter) percutaneous pneumatic driveline for each VAD is tunneled out of the body from the LVAD or RVAD in a pre- or intraperitoneal position. The major feature of this small pump is that it can be implanted to provide left, right, or biventricular support.

FIGURE 84.12. A: The HeartMate XVE (Thoratec Corporation, Pleasanton, CA) is an implantable, electrically driven, pulsatile, volume displacement left ventricular assist device designed for long-term mechanical circulatory support for bridge to transplant or destination therapy. B: Schematic representation of the preperitoneal pump placement for left ventricular assist and percutaneous drive line, external controller, and power source (batteries).

Implantable, Continuous Flow Mechanical Circulatory Support Devices (Rotary Pumps with Axial Flow Design)

Implantable, continuous flow rotary pumps with axial flow design represent the second generation of implantable VAD technology and have now replaced first-generation, pulsatile devices for long-term MCS indications.^{46,94-96} The term “second-generation rotary pump” has largely been used to describe those continuous flow rotary pumps, typically with an “axial” blood flow path, that have an internal rotor within the blood flow path that is suspended by contact bearings. Rotary pumps with axial flow design offer several advantages over pulsatile, volume displacement pumps. These advantages include smaller size, fewer moving parts, durability, absence of valves to direct blood flow, smaller blood-contacting surfaces, and reduced energy requirements. Blood flow is accomplished by the spinning of an internal rotor at high speed that imparts significant kinetic energy to the blood. The spinning of the rotor is accomplished by actuating an electrical current and magnetic field around the rotor that contains internal magnets. Blood flow from the left ventricle to the aorta occurs continuously during the systolic and diastolic phases of the cardiac cycle. Although blood flow is continuous during the cardiac cycle, phasic changes in the flow of blood occur during the cardiac cycle due to changes in ventricular pressure and aortic afterload. These phasic changes in blood flow impart a diminished pulsatility to the aortic waveform. The ability to design smaller pumps using axial flow technology is a result of the elimination of a large blood chamber necessary with pulsatile systems. An additional important feature of these pumps is the lack of need for a compliance chamber. This feature alleviates the problem of internal compensation that is associated with conventional

FIGURE 84.13. A: The Thoratec pVAD (Thoratec Corporation, Pleasanton, CA) is a pneumatically driven, paracorporeal, pulsatile, volume displacement pump designed for temporary univentricular or biventricular support for bridge to recovery or bridge to transplantation. **B:** Schematic representation of the Thoratec pVAD for biven- tricular support. LVAD, left ventricular apex to aorta; RVAD, right atrium to pulmonary artery.

pulsatile pumps that, to date, has significantly hindered total internalization.

Device designs incorporating second-generation rotary pump technology with an axial blood path have accumulated significant human clinical experience and are either currently in late stages of clinical trials in the United States or have been recently been approved by the FDA for BTT. Reports from clinical trials of the second-generation rotary pumps have demonstrated efficacy in providing hemodynamic support, a favorable risk-to-benefit assessment, and improvement in mechanical performance.^{46,96} Further, the human experience with second-generation rotary pumps with axial design has established the long-term safety of mechanical circulatory support with minimal pulse pressure.^{97,98} Results from clinical studies have demonstrated early improvement followed by long-term stability of renal and hepatic function and no adverse effects on neurocognitive performance.⁴⁶ These improvements in device technology with the second-generation of continuous flow rotary pumps with axial design have increased the acceptance of LVAD therapy for long-term MCS indications.

HeartMate II. The HeartMate II is a continuous flow rotary pump with axial design that is representative of the second generation of LVAD technology in clinical use in the United States⁴⁶ (Fig. 84.15). The HeartMate II recently completed an FDA evaluation for BTT therapy in the United States in a cohort of 133 patients. To date, over 400 patients have been evaluated with the HeartMate II LVAD for BTT therapy and the device has received approval by the FDA for BTT indication in May 2008. In an extended follow-up report of 280 patients evaluated for BTT therapy with the HeartMate II device, 222 patients (79%) either received a transplant, recovered cardiac function and underwent device explantation, or remained alive with ongoing LVAD support at 18-month follow-up.⁹⁹ At 18 months, 157 (55.8%) patients had received a heart transplant, 58 (20.6%) remained alive with ongoing LVAD support, 56 (19.9%) died, 7 (2.5%) recovered cardiac function and underwent device explantation, and 3 (1%) were withdrawn from the study after device explantation and exchange for another type of LVAD. Overall survival

FIGURE 84.15. A: The HeartMate II LVAD (Thoratec Corporation, Pleasanton, CA) is an implantable, continuous flow rotary left ventricular assist device with axial design intended for long-term mechanical circulatory support for bridge to transplantation or destination therapy. for the patients who continued on LVAD support was 82% (95% confidence interval [CI]: 77% to 87%) at 6 months, 73% (95% CI: 66% to 80%) at 1 year, and 72% (95% CI: 65% to 79%) at 18 months.

Jarvik 2000. The Jarvik 2000 (Jarvik Heart, Inc., New York, New York) is an implantable, continuous flow rotary pump with axial flow design.^{100–102} The unique feature of the Jarvik device is the placement of the pump within the left ventricle to eliminate the inflow cannula along with orientation of the outflow graft to the descending aorta (Fig. 84.16). The Jarvik 2000 pump is inserted through a sewing cuff sewn into the apex of the left ventricle. The outflow orifice of the pump is attached to a Dacron graft for anastomosis to the descending thoracic aorta. The current adult version of the Jarvik 2000 measures 2.5 cm in diameter by 5.5 cm in length, with a weight of 85 g and a displacement volume of 25 mL. The adult pump functions at speeds of 8,000 to 12,000 rpm, achieving blood flow up to 8 L/min. Percutaneous power is delivered from external batteries via a controller unit. Internal electrical wires are brought via the left pleural cavity to the apex of the chest and then subcutaneously across the neck to the base of the skull, where a percutaneous titanium pedestal transmits fine electrical wires through the skin of the scalp. The Jarvik 2000 LVAD is currently in clinical trial.

DeBakey Left Ventricular Assist Device. The DeBakey is an axial flow pump that measures approximately 86 mm long and 25 mm wide (about the size of an AA battery).^{95,103–105} It weighs 95 g and has a displacement of 15 cm³. The pump is designed to produce flows of 5 L/min against 100 mm Hg pressure with a rotor speed of 10,000 rpm with less than 10 W of power. The DeBakey LVAD is currently under investigation in clinical trial.

Implantable, Continuous Flow Mechanical Circulatory Support Devices (Rotary Pumps with Centrifugal Flow Design). Although significant improvements in pump design have occurred with the second generation of rotary pumps with an axial blood flow path, there remain potential concerns with this technology. The presence of contact bearings in the blood path that suspend the rotor represents a potential point of frictional wear resulting in device failure and subse-

quent need for device exchange.^{94,106} The second-generation rotary pumps with axial design still demonstrate the potential for thrombus formation on the device rotor and bearing interface due to the presence of stasis and incomplete “wash” of the bearings.^{46,95,107} The presence of stators to suspend and redirect blood flow also represents an obstruction within the blood flow path. Clinical studies have documented the problem with device thrombus requiring device exchange or treatment with thrombolytic therapy, and have also shown a reduced but persistent risk of stroke.^{46,107} In addition, this technology still requires long-term antithrombotic therapy and, subsequently, hemorrhagic complications are observed with this therapy.^{46,95,96}

FIGURE 84.16. The Jarvik 2000 (Jarvik Heart Corporation, New York, NY) is an implantable, continuous flow rotary left ventricular assist device with axial design intended for long-term mechanical circulatory support for bridge to transplant or destination therapy. Schematic representation of the placement of the Jarvik 2000 within the left ventricle.

An additional potential concern of second-generation rotary pumps with axial design is related to their hydrodynamic performance. To observe changes in pump flow at a fixed rotor speed, significant changes in pressure across the inlet and outlet orifices of the pump must occur.^{108,109} This relative degree of insensitivity of the hydrodynamic performance of the pump or “steep” pressure–flow relationship can result in left ventricular collapse and “suction” when filling pressures are abruptly reduced, as in the case of a sudden onset of a ventricular arrhythmia, or result in elevated filling pressures with dyspnea when return to the left atrium is abruptly increased, as with exercise. Left ventricular collapse or “suction” events can, by themselves, precipitate serious ventricular arrhythmias,¹¹⁰ and the inability to significantly increase pump flow with exercise may limit exercise performance in patients with axial pumps.

Implantable LVADs that are rotary pumps of centrifugal flow design represent the third generation of VADs. These devices provide continuous flow at rotational speeds that are much slower, about 2,000 to 4,000 rpm, compared to 8,000 to 15,000 rpm for pumps with axial flow design. The same general advantages and disadvantages of design features that apply to rotary pumps with axial flow design apply to centrifugal flow design. The major feature of the third generation of rotary pumps with centrifugal flow design is that the impeller is rotated and levitated in a magnetic field, eliminating the need for bearings and the subsequent problems associated with bearing wear; these pumps have a potential for very long durability.^{94,106,111} (Fig. 84.17). Impeller rotation to elicit blood flow is achieved through magnetic coupling to the pump motor. Levitation systems utilized in third-generation rotary pumps suspend the moving impeller within the blood field without any mechanical contact, thus eliminating frictional wear and reducing heat generation that would normally take place at the contact surface with a contact bearing design. These levitation forces may be achieved through magnetic or hydrodynamic bearing design. Magnetic forces may be passive without the consumption of power (permanent magnet) or active (induction of magnetic field with electricity) in design.^{94,106,111,112} Hydrodynamic levitation depends on fluid forces generated by the rotating impeller to levitate the internal impeller. Pump designs can be further distinguished by the utilization of hydrodynamic levitation only, hydrodynamic levitation working in synergy with magnetic levitation for suspension, or variations of active and/or passive magnetic levitation. Active magnetic levitation of the impeller typically utilizes complex position sensing and control systems that increase requirements for a larger pump size. Hydrodynamic suspension does not utilize position sensors, resulting in a less complicated electronic design and ability to miniaturize pump size. The design of any levitation system must be adequate to control the 6 degrees of freedom of movement of the suspended impeller.

FIGURE 84.17. Schematic representation of a third-generation continuous flow rotary pump utilizing magnetic coupling of the internal impeller for levitation and rotation that obviates the need for bearings in the blood flow path.

The third generation of rotary pumps with centrifugal design have a more sensitive pressure–flow relationship as compared to the second generation of rotary pumps with axial design.^{111,113} This greater sensitivity of the pressure–flow relationship results in greater changes in flow for any given change in pressure across the inlet and outlet orifices of the pump. This greater pump response to changes in flow may increase the margin of safety from creating suction events and improves pump flow during increases in left atrial return, potentially enhancing exercise response.^{114,115} The improvements in the design attributes of the third generation of rotary pumps with centrifugal design, such as mechanical wear, operation at low flow, and perceived improved potential for hemocompatibility while still maintaining a manageable size warrant further clinical investigation. Whether these attributes will result in significant improvement in clinical outcomes over that observed with the second generation of rotary pumps with axial design is not known at this time.

DuraHeart. The DuraHeart (Terumo Heart Corporation, Ann Arbor, Michigan) is a continuous flow rotary pump with centrifugal and noncontact bearing design^{106,112,113,116} (Fig. 84.18). The device has a displacement volume of 180 cm³ and a weight of 540 g. Its external dimensions are 72 mm in width and 45 mm in height. The pumping unit consists of an upper housing with the levitation system, an impeller, and a bottom housing containing the external drive motor. The device is designed with active magnetic levitation of the impeller along with hydrodynamic bearings to support impeller levitation in case of failure of the magnetic levitation system. The impeller is rotated through magnetic coupling between permanent magnets embedded on the motor side of the impeller and an external drive motor that utilizes a bearing design. Three electromagnets and three position sensors are mounted in the upper housing. Tilting and axial displacements of the impeller are monitored and controlled using a 3-degrees-of-freedom control. The ferromagnetic ring on the opposite side of the impeller is levitated by the electromagnet, and position sensors

FIGURE 84.18. (Photograph courtesy of HeartWare Corporation, Miami, FL.)

control the impeller so that it is always positioned at the center of the blood chamber. Radial impeller movement is passively suspended with a bias flux through the electromagnetic rotor and drive magnet rotor.

Clinical evaluation of the DuraHeart device has recently concluded in Europe and the device is undergoing clinical evaluation in the United States. A preliminary report of the European experience was recently presented at the International Society of Heart and Lung Transplantation in April 2008.¹¹⁶ Thirty-five patients with advanced heart failure (NYHA class IV, 14 ischemic, 5 females) who were eligible for heart transplantation underwent implantation of the DuraHeart device from January 2004 through September 2007. Median age of the patients was 56 (range, 29 to 73) years. The average duration of device support was 330 ± 220 (17 to 808) days with a cumulative duration of 21 years. Fourteen patients (40%) underwent heart transplantation at 194 ± 146 days. Nineteen patients (54%) were supported for at least 6 months and seven (20%) patients were supported for greater than 1 year. Fourteen patients (40%) remained alive with ongoing device support (330 ± 292 days). Kaplan-Meier survival at 2 years was 78%. There were seven deaths (median time to deaths, 29 days). Six early deaths occurred in the initial 11 patients and 4 were associated with excessive anticoagulation/antiplatelet therapy that resulted in fatal intracerebral hemorrhage or subdural hematoma. After implementing less intensive anticoagulation and antiplatelet therapy comparable to mechanical heart valves, there was no ischemic or hemorrhagic stroke for the last 24 patients. Stroke-free survival for the last 24 patients was 94% at 2 years. Twenty-six patients (86% of 1-month survivors) were discharged home, and the readmission rate was 1.5 patients per year.

HVAD. The HVAD (HeartWare Corporation, Miami, Florida) is a small continuous flow rotary pump with centrifugal and

noncontact bearing design. The unique feature of the HVAD is its small design size^{117,118} (Fig. 84.19). It has a displacement volume of 45 mL and weighs 145 g with a flow capacity of up to 10 L/min. The device is small enough to place within the pericardial cavity without the need for dissection and creation of a preperitoneal pocket. The impeller of the HVAD is suspended in place by combination of passive magnetic and hydrodynamic bearing systems. The impeller suspension system uses a passive magnetic bearing for radial stiffness. Axial magnetic preload and hydrodynamic bearings on top of each impeller blade provide axial constraint. The magnetic bearing consists of a stack of rare-earth ring magnets near the impeller's inside diameter that repel the magnetic force of a similar stack of magnets inside the center post. The axial alignment of the center-post magnet stack is set to provide an axial force that pushes the impeller toward the forward housing (the assembly with the inflow cannula). Physical contact between the housing and the impeller is prevented by a thin blood film generated by the hydrodynamic bearings.

The HVAD has undergone clinical evaluation in Europe and Australia and is undergoing clinical evaluation in the United States. In a multi-institutional trial in Europe and Australia, 20 patients underwent implantation of the HVAD from March 2006 through September 2007.¹¹⁷ Mean age of the patients was 46 ± 12 (range, 28 to 68) years. Mean duration of HVAD device support was 167 ± 143 days (range, 13 to 425 days). Range of blood flow provided by the pump was 4.0 to 6.5 L/min. Three patients were successfully transplanted after 426, 349, and 157 days, respectively. One patient was weaned from pump support on postoperative day 266, two patients died on device (postoperative days 13 and 203), and 14 patients remained alive with ongoing device support. Actuarial survival at 1 year was 80%.

Levacor. The Levacor (World Heart Corporation, Oakland, California) device is a continuous flow rotary pump with

FIGURE 84.20. A: The CardioWest total artificial heart (SynCardia Systems Corporation, Tucson, AZ) is a pneumatically driven, pulsatile, volume displacement device. **B:** The device is positioned orthotopically as a complete replacement of the native heart. The device is powered by drivelines that exit the anterior abdominal wall and connect to a large drive console.

centrifugal and noncontact bearing design.^{106,119} The pump is 35 mm high and 75 mm in diameter and weighs 440 g. The magnetic levitation system utilizes a combination of permanent magnets that provide passive levitation and a magnet coil that provides active levitation along 1 degree of freedom of movement of the impeller. Aside from rotation, the other 5 degrees of freedom of movement of the pump rotor are all passively controlled except axial movement in the z-direction, which is actively controlled by the coil and electronics. The motor is integrated directly into the pump housing and rotor and no external motor is required for rotation.

Clinical evaluation of the Levacor device has been initiated in Europe and Canada with successful results reported in a BTR protocol.¹¹⁹ Clinical evaluation in the United States is scheduled for 2010.

Total Artificial Hearts

CardioWest Total Artificial Heart. The CardioWest TAH (SynCardia Systems Corporation, Tucson, Arizona) is a pulsatile, volume displacement, total artificial heart^{120–123} (Fig. 84.20). The rigid polyurethane pump contains a flexible polyurethane diaphragm that separates blood and air chambers. Two Medtronic-Hall mechanical valves located at the inflow and outflow orifices ensure unidirectional blood flow. Compressed air from the external drive console moves the diaphragm upward, pressurizing the blood chamber and causing ejection of blood. The pump has a maximum stroke volume of 70 mL and a maximum flow rate of 15 L/min, although the average flow rate is less than 8 L/min. Pump rate, duration of systole, and driving pressure can be adjusted to achieve optimal flow conditions. The TAH is surgically implanted in the mediastinal space after the ventricles have been excised, while the atrial cuffs are retained. The pneumatic drivelines are externalized percutaneously and attached to the drive console. Patients may be ambulatory, but their mobility is frequently restricted by the large drive console. A portable drive console is in clinical trial evaluation. The CardioWest TAH is approved by the FDA for bridge to heart transplant indication. In a recent study, Copeland et al. reported a 79% survival to heart transplantation compared to 46% for the observational arm.¹²¹ One-year posttransplant survival was 86%.

Abiomed Total Replacement Heart. The AbioCor TAH (Abiomed, Inc., Danvers, Massachusetts) is an orthotopically positioned total artificial heart pump.¹²⁴ The system uses brushless DC motors that are powered by TETS (transcutaneous

energy transmission system), and the system is completely implantable with no need for percutaneous leads. Implanted nickel-cadmium batteries can also drive the system in case the external coils detach. The Abiomed TAH shifts hydraulic fluid to pump blood in a one-to-one fashion. A unidirectional centrifugal pump combined with a rotating valve transmits hydraulic fluid against one of the pump's diaphragms while simultaneously withdrawing fluid from the contralateral side. In this fashion, alternating filling and emptying of the pumps with blood occurs. The system incorporates 24-mL polyether urethane trileaflet valves in both the inlet and outlet orifices. The control schemes of this system demonstrate so-called Starling behavior so that increases in venous return elicit a commensurate increase in left pump output until a maximum output is reached. Optimal pumping rate is made a function of right atrial pressure, inferred from transducer-measured pressure readings within the right hydraulic chamber. Compensation for right and left flow imbalances depends on a flexible, 20-mL hydraulic chamber positioned against the left atrium. This compliance chamber, in continuity with the right pump's hydraulic chamber, exerts negative feedback on right pump filling. As left atrial pressure rises, hydraulic fluid shifts into the right hydraulic chamber, limiting the passive diastolic filling of the right pump's blood chamber. Less blood is then delivered to the left side until left atrial pressure decreases. The AbioCor TAH has received humane device exemption in the United States for clinical use for permanent replacement for patients not eligible for heart transplantation and at imminent risk of death from advanced heart failure.

FUTURE DIRECTIONS

Recent rapid technologic advancements and successful clinical applications of MCS have made the future of this field optimistic, but uncertain. It is possible that long-term MCS will provide a viable alternative to heart transplantation and medical therapy for patients with advanced heart failure. Due to the technologic advancements, it will be difficult to predict what devices will ultimately prove to be the most efficacious. It is likely that a variety of devices will become available for use depending on clinical circumstances and patient characteristics.

CHAPTER 85 ■ PERICARDIUM

JULES LIN

KEY POINTS

- 1 Prompt recognition and treatment of cardiac tamponade can be lifesaving.
- 2 The echocardiogram is the most useful noninvasive test in evaluating pericardial disease.
- 3 The electrocardiogram is important in the diagnosis of acute pericarditis and classically shows diffuse ST elevations.
- 4 The hemodynamic significance of a pericardial effusion depends on the volume and the rate of accumulation.
- 5 Postoperative tamponade should always be in the differential diagnosis with low cardiac output after cardiac surgery.
- 6 Distinguishing constrictive pericarditis from restrictive cardiomyopathy can be difficult, but is important since the treatment is significantly different.
- 7 Metastatic disease is the most common cause of pericardial effusion.

The pericardium supports and protects the heart. The smooth pericardial surface and the small amount of normal pericardial fluid provide a frictionless chamber, which improves cardiac efficiency and serves as a barrier to infection. The pericardium can be susceptible to a variety of disease processes including inflammation, infection, malignancy, and trauma. Changes in compliance and the accumulation of pericardial fluid can impair cardiac function, and its prompt recognition and treatment can be lifesaving.

HISTORY

Hippocrates first described the pericardium in 460 BC. Three hundred years later, Galen described a pericardial effusion and the inflammatory changes associated with pericarditis. Lower first reported pericardial tamponade in humans in 1669. Lancisi and Morgagni described constrictive pericarditis, and Laennec wrote of the “bread and butter” appearance of acute pericarditis in 1819.¹ Kussmaul described the hemodynamic changes known as pulsus paradoxus, and Beck and Griswold performed experimental studies in the 1930s leading to a better understanding of the pathophysiology of pericardial effusion.^{2,3} Karanaeff first described relieving the symptoms of tamponade using pericardiocentesis in 1840,⁴ and Rehn reported methods to resect the pericardium in 1913.⁵

EMBRYOLOGY AND ANATOMY

The pleuropericardial membranes fuse during the fifth week of gestation, dividing the thoracic cavity into pleural and pericardial spaces and forming the fibrous pericardium.⁶ The serous pericardium is a single layer of mesothelial cells that produce and reabsorb pericardial fluid. The serous and fibrous pericardium form the parietal pericardium, which is normally 2 mm in thickness. The visceral pericardium covers the heart and the intrapericardial great vessels. The phrenic nerves are contained in the parietal pericardium, and there is a risk of diaphragmatic paralysis with any operation on the pericardium. The pericardial folds form the oblique sinus, a blind cul-de-sac behind the left atrium, and the transverse sinus between the aorta and pulmonary artery superiorly and the left and right atrium inferiorly (Fig. 85.1). Lymphatic drainage is to the bronchial and tracheal lymph nodes and the thoracic duct. The

pericardium normally produces 15 to 50 mL of serous fluid with a protein level lower than plasma.⁷

NORMAL PHYSIOLOGY

Although there are no significant consequences of the congenital absence or surgical resection of the pericardium as long as the defect does not lead to cardiac herniation, the pericardium has some function in the normal patient. The pericardium anchors the heart and prevents torsion and acute distention.⁸ The pericardium also contributes to the diastolic coupling of the ventricles along the Starling curve. Mechanoreceptors in the pericardium may also regulate blood pressure and heart rate. The pericardium stretches up to 20% with small changes in pressure but becomes abruptly stiff and resistant with larger volumes. Compliance depends on the rate of fluid accumulation, and the hemodynamic response is also partially dependent on intravascular volume status.

The normal pericardial pressure is less than atmospheric pressure and is the same as the intrapleural pressure. With inspiration, right-sided venous return and preload increase. Blood pools in the lungs and decreases left-sided venous return and aortic blood flow. The arterial pressure normally decreases less than 10 mm Hg with inspiration. The normal jugular waveforms are shown in Figure 85.2. The a wave is the normal atrial contraction. The c wave reflects the bulging of the atrioventricular valve into the atrium during isovolumic ventricular systole. The v wave represents passive atrial filling from the vena cava. The x descent occurs with systolic collapse during ventricular systole and atrial relaxation. The y descent reflects diastolic collapse with opening of the atrioventricular valve and passive ventricular filling. Inspiration decreases intrathoracic pressure and leads to a lower x descent compared to the y descent.

DIAGNOSTIC STUDIES

While the electrocardiogram (ECG) is nonspecific, it can be helpful in suggesting the diagnosis. In acute pericarditis, the ECG classically shows diffuse ST elevations, and a low-voltage QRS is seen with a large pericardial effusion. The chest radiograph in a patient with a pericardial effusion shows an enlarged cardiac silhouette described as a water bottle. Pericardial calcification can

FIGURE 85.1. This drawing illustrates the pericardial attachments of the great vessels and pulmonary veins. The oblique sinus forms a blind cul-de-sac behind the left atrium, and the transverse sinus is a space between the aorta and pulmonary artery superiorly and the left and right atrium inferiorly. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1521.)

be seen in chronic constrictive pericarditis secondary to tuberculosis.

- 2 The echocardiogram is the most useful noninvasive test in evaluating pericardial disease. The echocardiogram can identify an effusion, pericardial thickening, or masses. By using Doppler and assessing changes in chamber size, the echocardiogram is useful in assessing hemodynamics and can help differentiate tamponade, constriction, and restriction. It can also be used to help guide procedures such as pericardiocentesis. Computed tomography (CT) and magnetic resonance imaging (MRI) can identify pericardial masses and pericardial thickening or calcification.⁹ Cardiac catheterization provides pressure tracings that help to distinguish cardiac tamponade, constriction, and restriction. Endomyocardial biopsy can also be useful in diagnosing restrictive cardiomyopathy.

CONGENITAL ABNORMALITIES

Congenital absence of the pericardium is usually partial, but can be complete. It is most common on the left side and is more frequent in males. Associated congenital cardiac defects include atrial septal defect, a bicuspid aortic valve, and pulmonary malformations. Defects on the right side can lead to cardiac herniation. Patients can present with chest pain, syncope, or death. The electrocardiogram can show a right bundle branch block. The pericardial defect can be appreciated on CT or MRI. The treatment of a partial defect is total pericardiectomy or patch closure with polytetrafluoroethylene or bovine pericardium. Total pericardial absence is usually asymptomatic and is found incidentally.

Pericardial cysts are rare benign cysts that generally measure 1 to 15 cm in size. They are most commonly found at the right cardiophrenic angle and are asymptomatic. Patients may present with mediastinal compression and respiratory symptoms. The differential diagnosis includes a Morgagni hernia,

lipoma, mediastinal tumor, or bronchogenic cyst. CT scans are used to confirm the location and relationship to surrounding structures. The cyst is excised if the patient is symptomatic or the diagnosis is unclear.

ACUTE PERICARDITIS

Acute pericarditis is an inflammatory process that has involved the pericardium for less than 2 weeks (Table 85.1). Patients often present with a 3- to 7-day prodrome of low-grade fevers, malaise, and muscle aches. Acute pericarditis occurs in 5% of those who present to the emergency department with nonischemic chest pain¹⁰ and in 1% of those with ST elevation.¹¹ It is important to distinguish pericarditis from the chest pain of an acute myocardial infarction. Acute pericarditis usually causes sharp, pleuritic pain that can last several days. The pain most commonly radiates to the trapezius ridge and is improved by leaning forward. Patients can present with shortness of breath, a nonproductive cough, and clear lung fields. The differential diagnosis also includes aortic dissection and pneumothorax. On physical examination, a friction rub may be heard and is sometimes intermittent. The classic friction rub has three components during systole, early diastolic filling, and atrial contraction.

- 3 The electrocardiogram is important in the diagnosis and classically shows diffuse ST elevations without Q waves or T-wave inversion. PR depression can also be seen. There is a four-stage progression in the changes seen on ECG, with diffuse ST elevations followed by normalization of ST segments with flattening of T waves. The ECG then evolves with T-wave inversions prior to normalization of the ECG. Pericarditis and associated myocarditis can cause elevations in creatinine kinase and troponin I.¹² The minimal workup should include an ECG, complete blood count, cultures, chemistry profile, and antibody titers for collagen diseases.

TABLE 85.1 ETIOLOGY**CAUSES OF PERICARDITIS**

Idiopathic
Infectious
Neoplastic
Hemopericardium
Blunt and penetrating trauma
Post–cardiac surgery
Aortic dissection
Autoimmune and inflammatory
Connective tissue disorders
Post–myocardial infarction
Medication induced
Miscellaneous
Radiation induced
Hypothyroidism
Uremic

Idiopathic and Viral Pericarditis

Idiopathic causes of pericarditis are the second most common after neoplastic disease. The majority are likely viral, although routine testing is not usually performed. A virus is only identified in 15% to 20% of cases, with the most common being coxsackievirus, echovirus, adenovirus, influenza, and cytomegalovirus. Patients present with chest pain, malaise, and fever and often have an elevated erythrocyte sedimentation rate. The episode is self-limited in 70% to 90% of cases.¹⁰ Initial treatment is with nonsteroidal anti-inflammatory drugs (NSAIDs). There is a 15% to 30% relapse rate, at which point specific causes, such as autoimmune disorders, should be investigated.^{10,13} A repeat course of NSAIDs, colchicine, or steroids is generally successful. Pericardiectomy is recommended if the patient is unresponsive to medical treatment or constriction develops.

Acquired Immunodeficiency Syndrome

A pericardial effusion develops in up to 20% of patients with human immunodeficiency virus (HIV) and is usually a poor prognostic sign.¹⁴ This may be partly due to a generalized capillary leak syndrome as well as increased cytokine expression seen in the more advanced stages of HIV. Other contributing factors include tubercular and mycobacterial infections, lymphoma, Kaposi sarcoma, or congestive heart failure. The majority are idiopathic and do not require further therapy if asymptomatic. Symptomatic effusions are drained.

Tuberculous Pericarditis

Tuberculous pericarditis occurs in 1% to 8% of patients.¹⁵ In immunocompromised patients, infection by *Mycobacterium avium* or *Mycobacterium intracellulare* can lead to pericarditis. The incidence of tuberculous pericarditis has decreased, although it continues to be a significant issue in immunocompromised patients, particularly HIV patients in Africa. Patients present with fever, night sweats, cough, dyspnea, and weight loss. While infection usually results from hematogenous spread, it can also extend directly from lymph nodes or through lymphatics. Pericardial changes occur in four stages: fibrinous, effusive, fibrous, and constrictive fibrous. Making the diagnosis

from pericardial fluid alone is rare. Pericardial biopsy with acid-fast staining provides the diagnosis 80% to 90% of the time. Treatment includes multidrug antitubercular therapy and pericardiocentesis. Steroids have not been shown to be beneficial for mortality or progression to constriction, but lead to a faster resolution of symptoms and reaccumulation.¹⁶ If patients present with late constriction, pericardiectomy may be required.

Purulent Pericarditis

Bacteria can be introduced into the pericardial space by direct injury, pneumonia, extension from head and neck infections, or hematogenous and lymphatic spread. Patients present with chest pain, fever, and leukocytosis. The most common organisms in adults are staphylococcus, pneumococcus, and streptococcus. Purulent pericarditis can evolve rapidly into tamponade and can be confused with septic shock. Fungal infections are less common, but immunocompromised patients and drug addicts are at greater risk. Pericardial fluid in purulent pericarditis has low glucose, high protein, and elevated lactate dehydrogenase (LDH) and neutrophils. An air-fluid level may be seen on chest radiography with gas-producing organisms. Treatment includes antibiotics and drainage. Surgical drainage may be needed for thick fluid or refractory effusions. The prognosis for purulent pericarditis is poor, with a survival of 30%.^{10,17}

Uremic Pericarditis

Fifty percent of patients with untreated renal disease develop pericarditis. The incidence is decreased to approximately 20% in patients on hemodialysis. The exact cause is unknown but is not directly related to the blood urea nitrogen (BUN) or creatinine. Other possible etiologies include hypercalcemia, viral infection, and autoimmune disease. Chest pain is usually less common, and the large effusions accumulate gradually. Treatment includes more intensive dialysis, NSAIDs, and steroids. The fluid is generally bloody and care should be taken in heparinizing these patients for dialysis. If patients develop tamponade or the effusion is unresponsive, pericardiocentesis or surgical drainage is performed.

Vasculitis, Connective Tissue Disease, and Drugs

Pericarditis can result from a variety of vasculitic and connective tissue diseases, including rheumatoid arthritis, Wegener granulomatosis, rheumatic fever, lupus, scleroderma, Reiter syndrome, Behçet disease, dermatomyositis, polyarteritis nodosa, dermatomyositis, sarcoidosis, and amyloidosis. Treatment includes management of the underlying disease process and NSAIDs. Pericardiocentesis is performed if necessary. Several medications can also lead to pericarditis including warfarin, hydralazine, isoniazid, procainamide, phenytoin, dantrolene, cromolyn, and methysergide.

Dressler and Postpericardiotomy Syndrome

Pericarditis can occur following acute myocardial infarction in 3% to 5% of patients.¹⁸ Pericarditis can develop early in the first 1 to 3 days, particularly with transmural infarction. Forty percent of large Q-wave infarctions cause pericardial inflammation, although the incidence is decreasing with the use of thrombolytics and early revascularization. Patients are usually asymptomatic and are found to have a pericardial rub on examination, although they can present with pleuritic chest

pain. Treatment is usually with NSAIDs. Steroids can prevent conversion of infarcted myocardium to scar, leading to greater thinning and risk of rupture.^{19,20}

Patients can also present with pericarditis 1 week to a few months after a myocardial infarction with a friction rub, typical ECG changes, and chest pain, although the incidence has decreased with increased revascularization. Pericardial inflammation is thought to be from an autoimmune reaction to myocardial cells.²⁰ Similar symptoms can also occur after cardiac surgery, blunt trauma, and pacemaker placement. Patients can develop a pericardial effusion and even tamponade. Treatment includes NSAIDs and colchicine for 2 to 3 weeks and occasionally steroids. The syndrome is usually self-limited.

Radiation-induced Pericarditis

Pericarditis can result from mediastinal and thoracic radiation for cancer, including lymphoma and breast carcinoma, and is related to the dosage delivered. With modern techniques, the incidence is 2%, but can be as high as 20% if the entire pericardium is treated. Patients may develop chest pain and fever.²⁰ Symptoms are usually self-limited, and tamponade is rare. Delayed symptoms can develop years later and can result in pericardial constriction. Due to the history of malignancy, the etiology can be confused with a malignant effusion. If pericardial constriction develops, the treatment is pericardiectomy, although the mortality is higher than for other etiologies.

PERICARDIAL EFFUSION AND TAMPONADE

Any of the etiologies mentioned previously for pericarditis can also lead to pericardial effusion. Other causes include blunt or penetrating trauma, retrograde bleeding from an aortic dissec-

tion, and a transudative effusion from congestive heart failure. Effusions due to a bacterial or fungal infection, HIV, or malignancy have a higher incidence of progressing to tamponade. Twenty percent of large symptomatic effusions of unknown cause are due to an undiagnosed cancer.²¹

Normally there is only a small reserve volume before pericardial fluid causes significant cardiac compression and prevents adequate cardiac filling. The hemodynamic significance of a pericardial effusion depends on the volume and the rate of accumulation. The compensatory adrenergic response to a pericardial effusion leads to tachycardia and increased contractility, and patients on beta-blockers are less likely to compensate. Tamponade usually occurs when filling pressures reach 15 to 20 mm Hg, although tamponade can occur at lower pressures in conditions where blood volume is reduced, including dialysis, with diuretic therapy, and bleeding. Cardiac pressures become elevated and are most closely equalized during inspiration. Tamponade generally affects right heart filling first, which then leads to underfilling of the left heart.²²

Patients may present with dyspnea, tachycardia, and diaphoresis. The three classic signs of Beck's triad are hypotension, jugular venous distention, and muffled heart sounds, although each may be absent in patients with tamponade.²³ Symptoms can be confused with right heart failure and pulmonary embolus. The jugular waveform changes characteristically with loss of the y descent.²⁴ Since the total heart volume is fixed in tamponade, blood only enters the heart when blood leaves. The y descent represents opening of the tricuspid valve and is lost since no blood is ejected from the heart. Pulsus paradoxus is also noted with a fall in the systolic blood pressure of greater than 10 mm Hg with inspiration. Pulsus paradoxus is absent in left ventricular dysfunction, atrial septal defect, positive-pressure ventilation, aortic insufficiency, and regional tamponade. The ECG shows variation in the morphology of every other QRS complex, or electrical alternans, due to swinging of the heart in the pericardial effusion (Fig. 85.3). Chest radiography shows an enlarged, rounded cardiac

FIGURE 85.3. The 12-lead electrocardiogram shows electrical alternans with variation in the morphology of every other QRS complex in a patient with a large pericardial effusion. (Reproduced with permission from Joffe II, Jacobs LE, Kotler MN. Pericardial tamponade. *Circulation* 1996;94:2667.)

FIGURE 85.4. The echocardiogram shows a large pericardial effusion with diastolic right atrial collapse (*arrow*). (Reproduced with permission from Joffe II, Jacobs LE, Kotler MN. Pericardial tamponade. *Circulation* 1996;94:2667.)

silhouette. The pericardial fat pad sign is seen when the pericardial fat is separated from the heart by the effusion.

Echocardiography is the most useful test in diagnosing pericardial effusion and tamponade. Signs of tamponade include early diastolic right ventricular and right atrial collapse during diastole (Fig. 85.4) and distention of the cava that does not diminish with inspiration. Doppler is useful in evaluating blood flow and shows exaggerated respiratory variation with an increase with inspiration on the right and a decrease on the left side of the heart. Echocardiography is also useful in identifying localized atrial compression, which can lead to tamponade with the other changes described previously.

The approach to a patient with a large pericardial effusion is outlined in Algorithm 85.1. If there are significant hemody-

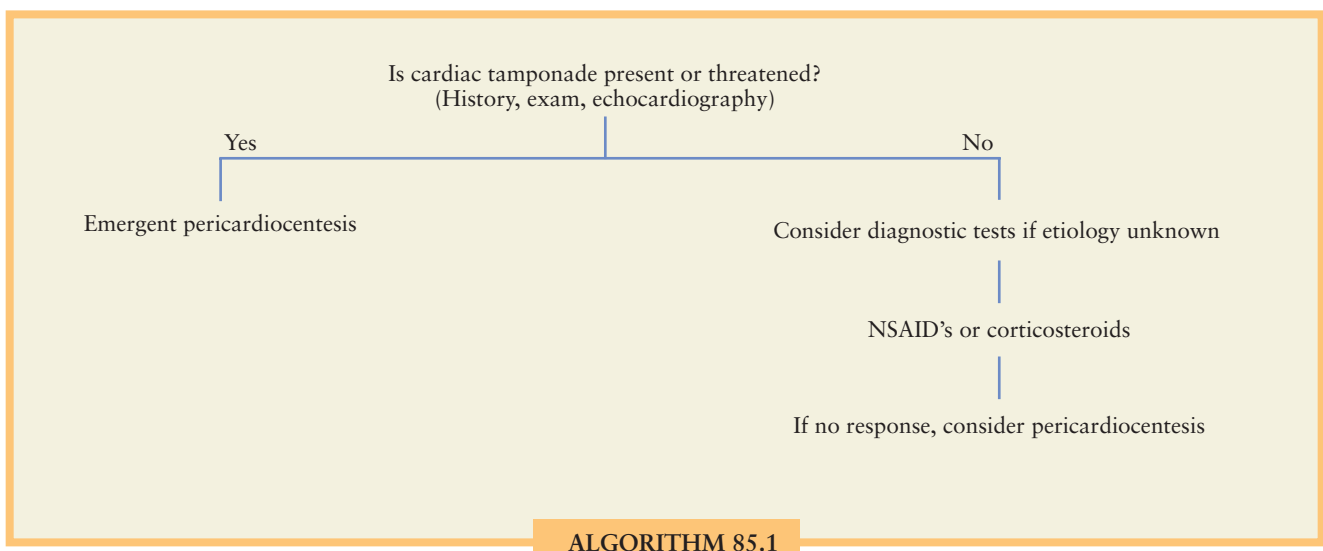

namic changes, emergent pericardiocentesis should be performed. Intravenous fluid and inotropes can temporize the hypotension but should not delay pericardiocentesis. If the effusion is loculated or contains blood clots, open drainage may be necessary. There should be a higher suspicion for tamponade in situations involving bleeding, bacterial or tuberculous pericarditis, or an acute or increasing moderate to large effusion.

Postoperative Cardiac Tamponade

- 5 Postoperative tamponade should always be in the differential diagnosis with low cardiac output after cardiac surgery. Patients may have rising filling pressures, hypotension, and decreased urine and cardiac output. Mediastinal chest tube output may increase or abruptly stop. Hypovolemia during the postoperative period can limit the increase in filling pressures. Pulsus paradoxus may also be masked by positive-pressure ventilation. On chest radiography, the cardiac silhouette is enlarged. In the postoperative cardiac patient, the epicardial pacing wires may move farther from the pericardium with increasing tamponade on chest films. Tamponade can result from relatively small amounts of blood with localized atrial compression from blood clots. There should be a low threshold for reexploration, which also provides a definitive diagnosis. Patients can also present with delayed tamponade after being started on anticoagulants.

PERICARDIAL CONSTRICTION

Constriction develops when the heart becomes constrained by a fibrotic pericardium. The process can progress over years, and the most common causes in the developed world are radiation treatment, postsurgical changes, and idiopathic. Tuberculosis was the most common cause before antitubercular drug therapy. Other causes include amyloidosis, scleroderma, sarcoidosis, hemochromatosis, and malignant disease. Patients develop signs and symptoms of right heart failure due to obstruction of the right ventricular outflow tract including hepatomegaly, ascites, and peripheral edema. Patients can also

ALGORITHM 85.1. This algorithm outlines the initial approach to a patient with a large pericardial effusion.

FIGURE 85.5. A: Chest computed tomography (CT) shows extensive pericardial calcification. (Reproduced with permission from Cavendish JJ, Linz PE. Constrictive pericarditis from a severely calcified pericardium. *Circulation* 2005; 112:e138.). B: Chest CT shows thickening of the pericardium in a patient with constrictive pericarditis. (Reproduced with permission from Tom CW, Oh JK. A case of transient constrictive pericarditis. *Circulation* 2005;111:e364.).

have dyspnea, pleural effusions, fatigue, and weight loss. On physical examination, a pericardial knock, or a loud third heart sound, can be heard, which corresponds to the abrupt cessation of diastolic filling. The Kussmaul sign is increased jugular venous distention with inspiration. Atrial fibrillation or flutter is present in up to 25% of patients, and tricuspid regurgitation is also common.

Pericardial calcification is pathognomonic but is only seen in 40% of cases. Thickened pericardium can be seen on CT or MRI (Fig. 85.5), although the pericardium was normal in thickness in 18% of patients in one series.²⁵ The normal pericardial thickness is 2 mm on CT and 4 mm on MRI. Echocardiography shows thickened pericardium and a septal bounce due to the abrupt displacement of the septum during early diastole. The ventricles are small with good function. Ventricular filling halts abruptly in diastole due to the limits of the stiff, fibrotic pericardium. There are signs of systemic venous congestion with a distended inferior vena cava. In contrast to tamponade, there is no decrease in early diastolic filling but a

sudden decrease in late diastole (Table 85.2).²⁴ When the myocardium is involved by fibrosis, ventricle dysfunction is present, which is associated with a poorer response to pericardiectomy.

On right heart catheterization, the y descent is deeper and more rapid than normal. The right atrial waveform is M- or W-shaped. The right ventricular tracing is described as the “square root” sign with an early diastolic decrease with a rapid increase and plateau (Fig. 85.6). Pulmonary artery and right ventricular pressures can be moderately elevated, but more severe pulmonary hypertension suggests a different disease process. In addition, hypovolemia can mask these findings, and patients may need to be volume challenged to see the diagnostic changes.²⁶

6 Distinguishing constrictive pericarditis from restrictive cardiomyopathy can be difficult, but is important since the treatment is significantly different (Table 85.3). In restrictive cardiomyopathy, there is no pericardial thickening. Decreased systolic function, mitral regurgitation, and left heart pressures

TABLE 85.2

DIAGNOSIS

DISTINGUISHING CARDIAC TAMPONADE AND CONSTRICTIVE PERICARDITIS

	■ TAMPONADE	■ CONSTRICTION
Pulsus paradoxus	Usually present	Present in one third of cases
Jugular venous waveform	Absent y descent	Prominent y descent (M or W)
Inspiratory changes in venous pressure	Decrease	Increase (Kussmaul sign)
Equal right and left pressures	Present	Present
“Square-root” sign of ventricular pressure	Absent	Present

FIGURE 85.6. A: The right ventricular (RV) pressure tracing shows elevated RV diastolic pressure with the dip-and-plateau waveform known as the “square-root” sign. The electrocardiogram tracing shows a large P wave indicative of right atrial enlargement. B: The postoperative RV tracing shows normalization of the RV waveform. (Reproduced with permission from Correa SD, Amsterdam EA. Constrictive pericarditis. *Circulation* 1998;97: 806.)

greater than right are more common in restrictive cardiomyopathy. Early diastolic filling is slower. In addition, left and right ventricular pressures move in the same direction on inspiration rather than in opposite directions.²⁷

Constrictive pericarditis is generally progressive, although it can be transient after cardiac surgery and should be observed for several months. Diuretics with fluid and salt restriction help initially, but pericardiectomy is the only definitive treatment. Tachycardia is a compensatory response, and beta-blockers and calcium channel blockers should be avoided.

NEOPLASTIC PERICARDIAL DISEASE

Primary tumors of the pericardium are rare and include benign fibromas, hemangiomas, lipomas, lymphangiomas, leiomyomas, and neurofibromas. Malignant pleural tumors include mesothelioma, teratoma, and fibrosarcoma. Surgical resection is therapeutic and diagnostic. Malignancies can also extend directly from the mediastinum, esophagus, and lung. Metastatic disease is the most common cause of pericardial effusion. Cardiac involvement is found in 5% to 10% of patients dying of cancer,

with 85% of those having pericardial involvement. The most common cancers are lung and breast carcinoma, lymphoma, melanoma, and leukemia. Patients often present with tamponade. The diagnosis is made on echocardiography or CT. Cytology of pericardial fluid is negative in 20% to 50% of cases, and pericardial biopsy may be helpful. Palliation includes sclerosing agents such as tetracycline, radiotherapy, intrapericardial chemotherapy, and catheter drainage.

PERICARDIOCENTESIS

Pericardiocentesis can be diagnostic and therapeutic. Ideally, it should be performed in the catheterization lab so the hemodynamic response can be monitored. Normal pericardial fluid is an ultrafiltrate with an LDH 2.4 times serum and protein 0.6 times serum.²⁸ Uremic fluid is bloody. Rheumatic effusions are high in protein and leukocytes and low in glucose. Cholesterol crystals are seen with myxedema, tuberculosis, and rheumatoid arthritis.

Generally, a 16- to 22-gauge needle is inserted to the left of the xiphoid. The needle is angled at 45 degrees toward the left shoulder (Fig. 85.7). An ECG lead may also be attached to the needle to monitor for an injury current, although

TABLE 85.3

DIAGNOSIS

DISTINGUISHING CONSTRICTIVE PERICARDITIS FROM RESTRICTIVE CARDIOMYOPATHY

	■ RESTRICTION	■ CONSTRICTION
Pericardial knock	Absent	Present
Pulsus paradoxus	Absent	Present in one third of cases
Thickened pericardium	Absent	Present
Atrial enlargement	Biatrial	Possibly left atrial
Septal bounce	Absent	Present
Equal right and left pressures	Left 3–5 mm Hg > than right	Present
Filling pressures >25 mm Hg	Present	Uncommon
Pulmonary artery SBP >60 mm Hg	Present	Absent
“Square root” sign of ventricular pressure	Variable	Present
Prominent y descent	Variable	Present

SBP, systolic blood pressure.

FIGURE 85.7. Pericardiocentesis is performed by inserting a needle to the left of the xiphoid and toward the left shoulder at a 45-degree angle. An electrocardiogram lead may be attached to the needle to monitor for Q waves indicating contact with the epicardium. (Reproduced with permission from Bradley SM. Pericardium. In: Mulholland MW, Lillemoe KD, eds. *Greenfield's Surgery: Scientific Principles and Practice*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1526.)

echocardiography is more commonly used for guidance. There is a 97% success rate with a complication rate of 4.7% (Table 85.4).²⁹ If the effusion is anterior, a parasternal approach is used 1 to 2 cm to the left of the sternum in the fourth or fifth intercostal space. The removal of even a small amount of fluid can lead to significant hemodynamic improvement. For longer-term drainage, a catheter can be placed over a guide wire. Pericardiocentesis may not be effective for purulent or bloody effusions, which may require open drainage.

TABLE 85.4 COMPLICATIONS

POTENTIAL COMPLICATIONS FROM PERICARDIOCENTESIS

Injury to surrounding organs
Liver laceration
Lung (pneumothorax)
Coronary arteries
Myocardium
Arrhythmias
Pulmonary edema from acute left ventricular failure
Recurrence

FIGURE 85.8. Open pericardial biopsy or drainage is performed through an upper midline incision. The xiphoid is retracted or removed, providing exposure to the pericardium. (Reproduced with permission from Bradley SM. Pericardium. In: Mulholland MW, Lillemoe KD, eds. *Greenfield's Surgery: Scientific Principles and Practice*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1527.)

PERICARDIAL BIOPSY AND SURGICAL DRAINAGE

Pericardial biopsy is useful when pericardiocentesis is nondiagnostic, which is not uncommon in neoplastic and tubercular effusions. This can be approached through a subxiphoid incision, through an anterior thoracotomy, or thoracoscopically (Fig. 85.8). Open drainage may be useful if the fluid is viscous, including bloody or purulent effusions or in patients who have recurrent effusions. Loculated effusions may also require open drainage. The subxiphoid approach is better for purulent effusions to prevent contamination of the pleural space. Chronic or malignant effusions can be drained through a pericardial window into the left pleura. Preinduction pericardiocentesis or intravenous fluids may be necessary for patients to tolerate general anesthesia.

PERICARDIECTOMY

Pericardiectomy is most commonly performed for constrictive pericarditis. It can be performed through a median sternotomy or a left anterior thoracotomy in the fifth intercostal space. Anterior thoracotomy allows removal of the pericardium over the left ventricle with minimal manipulation. Femoral cannulation is used if bypass is necessary. Median sternotomy is the most common approach (Fig. 85.9). Cardiopulmonary bypass increases the risk of bleeding and is used when significant cardiac manipulation is needed or the dissection is difficult. The pericardium over the left ventricle is resected first to avoid pulmonary edema from the right ventricle ejecting against a constricted left ventricle. The pericardium is removed from phrenic nerve to phrenic nerve. Some patients have an immediate improvement in hemodynamics and symptoms, while others do

FIGURE 85.9. Pericardiectomy is most commonly approached through a median sternotomy. **A:** The pericardium is incised and the fibrous pericardium dissected from the left ventricle. **B:** The heart is retracted to the right so that the pericardium can be resected from phrenic nerve to phrenic nerve. (Reproduced with permission from Bradley SM. Pericardium. In: Mulholland MW, Lillemoe KD, eds. *Greenfield's Surgery: Scientific Principles and Practice*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1527.)

not improve until weeks or months later. A delayed or incomplete response is thought to be due to an incomplete resection of the visceral pericardium or myocardial atrophy and fibrosis. Left ventricular function returned to normal in 40% of patients.

Perioperative mortality has been reported between 5% and 15% and is due to low cardiac output, sepsis, bleeding, and renal or respiratory failure.³⁰ Seventy percent of mortality is due to low cardiac output. Mortality is directly related to the patient's preoperative status³¹ and is 1% for New York Heart Association class I to II, 10% for class III, and 46% for class IV.³² Five-year survival is 84%, and 99% of late survivors were class I or II. Patients with constriction due to radiotherapy have a higher mortality rate, which may be due to radiation-induced myocardial injury. Other poor prognostic factors are renal failure, advanced age, pulmonary hypertension, hyponatremia, and reduced cardiac output.^{30,33}

CHAPTER 86 ■ VASCULAR DIAGNOSTICS

GREGORY L. MONETA

KEY POINTS

- 1 The noninvasive vascular laboratory in many ways is the scientific basis for the modern practice of vascular surgery.
- 2 Ultrasound techniques and in particular duplex ultrasound-based techniques have largely eclipsed plethysmographic techniques in most vascular laboratories.
- 3 Detecting carotid stenosis involves a combination of spectral analysis, color and grayscale imaging, and, in selected cases, power Doppler.
- 4 The noninvasive vascular laboratory, in combination with the history and physical examination, has a critical role in providing objective diagnosis of lower extremity arterial occlusive disease in asymptomatic patients, those with intermittent claudication, and those with critical arterial insufficiency.
- 5 The ankle-brachial index (ABI) is a very useful measure of overall lower extremity perfusion.
- 6 Arterial duplex scanning provides detailed anatomic and hemodynamic information from the infrarenal aorta to the distal tibial vessels that cannot be determined by indirect testing. The role of duplex ultrasound scanning in the surveillance of lower extremity vein grafts has been well documented.
- 7 Digital pressure measurements and digital plethysmography are extremely useful in the diagnosis of upper extremity arterial disease and can be as accurate as arteriography in assessing patients with hand ischemia.
- 8 Duplex ultrasonography can serve as a valuable noninvasive screening test for splanchnic artery stenosis in patients with possible chronic mesenteric ischemia and for follow-up of mesenteric artery reconstructions.
- 9 Physical examination is not sensitive or specific for the detection of acute deep venous thrombosis (DVT). At a minimum, vascular laboratory duplex ultrasound evaluation for lower extremity DVT should include examination of the common femoral, profunda femoral, femoral, and popliteal veins.
- 10 Vascular laboratory ultrasound screening of males older than 65 years with a history of cigarette smoking for abdominal aortic aneurysm (AAA) has been shown to be effective in preventing aneurysm-related deaths.

- 1 The noninvasive vascular laboratory in many ways is the scientific basis for the modern practice of vascular surgery. It provides accurate, safe, and objective evidence of the presence of vascular disease throughout the body and, in many cases, its physiologic significance. There are two broad categories of testing available in the noninvasive vascular laboratory: plethysmographic techniques and ultrasound-based techniques.

PLETHYSMOGRAPHY

Plethysmography is based on the detection of limb volume changes in response to arterial inflow. In addition to volume flow, the technology can be modified to determine digital pressures and produce pulse waveforms. Mercury strain gauge plethysmography, air plethysmography (pulse volume recordings), and photoplethysmography are examples of plethysmographic techniques used clinically.

ULTRASOUND

- 2 Ultrasound techniques and in particular duplex ultrasound-based techniques have largely eclipsed plethysmographic techniques in most vascular laboratories. Duplex ultrasound was introduced in 1974 and was applied first to the carotid artery. The term “duplex” derives from the fact that the technique combines information from ultrasound-generated images (B mode) and Doppler analysis of blood flow direction and velocity. Duplex ultrasound is used extensively in the modern evaluation of carotid arteries, intra-abdominal arteries, and veins as well as upper and lower extremity arteries and veins. Since its inception, the technique has been advanced by (a) improved B-mode imaging; (b) better low-frequency scan

heads, permitting deeper penetration of the ultrasound beam from the skin surface; (3) improvements in online computer-based microprocessor software; and (4) perhaps most importantly, the addition of color flow to the B-mode image.

In essence, color flow is superimposing a real-time color image of blood flow onto a standard grayscale B-mode picture. Returning echoes from stationary tissues generate the B-mode image, while those interacting with moving substances (blood) generate a significant enough phase shift that they can be processed separately and color-coded by operator selection to give information on the direction and velocity of blood flow according to the magnitude and direction of the Doppler frequency shift. It is color flow, combined with the ability of the current generation of duplex scanners to detect very low blood flow velocities (<5 cm/s), that makes duplex scanning practical on a routine basis throughout the body. Color flow dramatically reduces the time required to perform duplex examinations by allowing more rapid identification of vessels to be examined. It appears essential for duplex examination of some vessels such as tibial arteries and veins.

BASICS OF DUPLEX ULTRASOUND

An ultrasonic wave is produced in tissue by placing a vibrating source in contact with the tissue. This vibrating source is the ultrasound transducer. The transducer is contained within the ultrasound scan head. The purpose of the scan head is to steer and focus the sound beam arising from the transducer. These functions are crucial in deriving an ultrasound image from the returning echoes.

The transducer converts electrical energy into vibrational energy and, conversely, turns the vibrational energy of returning echoes into electrical signals that can be analyzed by the

software of the duplex machine. The frequency of the vibrations, which determines the wavelength of the resulting sound wave, is determined by the design of the transducer. The relationship between frequency and wavelength is expressed mathematically as follows:

$$\lambda = c/f \quad (86.1)$$

where λ is the wavelength, c is the speed of sound in tissue, and f is the frequency.

The speed of sound in soft tissues averages 1,540 m/s and varies only minimally from this average in the soft tissues insonated in the clinical application of duplex ultrasound. The wavelength of the sound beam as it moves through the tissue is the principal physical determinant of how well the ultrasound beam penetrates the tissue. Because the speed of sound within tissue is, for all practical purposes, constant (1,540 m/s), the ability of ultrasound to penetrate tissue depends on the frequency of the vibrating source (transducer). As noted earlier, transducer frequency is determined by the design of the transducer and is thus controlled by the manufacturer of the duplex device. For examination of the carotid artery, transducer frequencies of 5 to 7.5 MHz provide optimal tissue penetration for clinical purposes.

As noted earlier, the term “duplex” refers to the combination of Doppler and B-mode (“B” stands for “brightness”) ultrasound in the same device. Both types of ultrasound require analysis of reflected echoes of the original sound beam initially created by placing the ultrasound transducer in contact with the tissue. The B-mode component of the duplex machine is most concerned with analyzing the strength (intensity) and origin of the reflected echo, while the Doppler component is most concerned with analyzing shifts in frequency of an original sound wave produced by the transducer.

B-mode Ultrasound

As a sound wave passes through tissue, its relative strength at any point as it moves away from the transducer depends on the degree to which the beam has been attenuated, scattered, and reflected up to that point. The strength of the reflected echo depends in part on relative differences in acoustic impedance between two different media. Major differences in acoustic impedance reflect a large proportion of the sound beam back to the transducer, while small differences result in little reflection and continued propagation of the beam through the tissue.

In B-mode ultrasound, the strength of the returning echo is reflected in the brightness of the individual pixels comprising the ultrasound image. This is the ultrasound grayscale and the resulting image is termed a grayscale image. (As we will see later, the primary purpose of the grayscale image in duplex ultrasonography is to aid in properly positioning the Doppler sample volume.)

Very bright pixels represent sites of large differences in acoustic impedance between media, while less dramatic differences are represented by proportionally less bright pixels on the B-mode image. Thus, gallstones, which differ dramatically in acoustic properties from soft tissue, result in strong echoes and proportionally brighter pixels on an ultrasound image, while blood, which differs little from soft tissue in acoustic characteristics, frequently cannot be distinguished from soft tissue in a grayscale image.

Of course, the strength of the reflected echo will also be dependent on the strength of the sound beam at the point of its reflection. Grayscale images do not show the percentage of the beam reflected, but rather represent the absolute strength of the reflected echo arriving back at the transducer. Thus, if the sound beam is very weak at the site of its reflection, even areas of significant differences in acoustic impedance will not result in a bright pixel on the ultrasound image.

In addition to reflection, the strength of the ultrasound beam at any point also depends on the degree to which the beam has been attenuated as it passes through the tissue. Attenuation of a sound wave in tissue depends on both the tissue traversed and the frequency of the wave. The frequency of the wave depends on the frequency of the transducer used to generate the wave (see discussion earlier and Equation 86.1). In any given tissue, sound waves resulting from higher-frequency transducers are attenuated more rapidly than sound waves resulting from lower-frequency transducers. Higher-frequency transducers therefore provide a relatively weak echo to be reflected from a deep structure and thus a comparatively poor B-mode image compared to a lower-frequency transducer.

The linear resolution of an ultrasound image depends on the ability to focus the beam. Sound beams emanating from high-frequency transducers can be more precisely focused than those from low-frequency transducers and thus provide clearer B-mode images of more superficial structures. Because the carotid artery is superficial, higher-frequency transducers can be used to provide much clearer B-mode images than is possible with deeper vessels such as the aorta or iliac arteries.

Doppler Ultrasound

In a continuous wave Doppler, a transducer continually emits vibrations into the tissue. Echoes are therefore continually reflected back to the transducer. A transducer cannot, however, simultaneously generate and receive an echo. A continuous wave Doppler therefore must have separate transmitters and receivers to both generate and receive echoes.

Duplex devices utilize pulse Doppler. A pulse Doppler uses the same transducer to generate and receive echoes. Because the speed of sound is relatively constant in tissue, and with a pulse Doppler it is possible to know when an echo is generated and when it is received, it is possible to tell from what depth in the tissue a reflected echo originated. The sample volume of the duplex device is thus determined by specifying from what depth one wishes the pulse Doppler to receive reflected echoes.

The transducer is gated, based on the total time from original sound wave generation to arrival of the reflected echo back at the transducer, to only receive echoes from the specified depth of the sample volume. The “position” of the sample volume is determined from the B-mode image, and in duplex examination of a blood vessel corresponds to particular points within the lumen of the vessel examined. Because B-mode images and Doppler waveforms cannot be generated simultaneously, the technologist must continually update the B-mode image during the course of the examination to ensure proper placement of the sample volume.

When a sound wave encounters moving reflectors, such as red blood cells within the lumen of an artery or vein, the frequency of the reflected wave changes from that of the original wave generated by the transducer. The magnitude of this frequency shift depends on the velocity of the moving reflector and its angle with the incident sound beam. Because the frequency of the original sound wave is known and the frequency of the received echo can be determined by the software of the duplex machine, the velocity of the moving reflectors (red blood cells) can be calculated provided the angle of the incident sound beam with the moving reflectors is also known. This relationship is reflected in the Doppler equation:

$$f_r - f_o = [(2f_o v)/c] \cos \theta \quad (86.2)$$

where f_r is the received frequency, f_o is the originating frequency, v is the velocity of the reflector, c is the speed of sound in tissue, and θ is the angle of the incident sound beam with the moving reflectors, the so-called Doppler angle.

To solve the Doppler equation for the velocity of the moving reflectors, the Doppler angle must be known. To standardize the results of duplex scanning, it has been traditionally

FIGURE 86.1. Color flow image of a normal carotid bifurcation. The color bar on the right of the image indicates that flow toward the probe is blue and away from the probe is red. Note that the black line separating the blue and red on the color bar indicates no Doppler shift. Therefore, when the color on the image goes from red to black to blue, this indicates true flow reversal. The area of reverse flow on the lateral wall of the carotid bulb opposite the flow divider in this image is a normal finding and indicates a carotid bulb free of significant atherosclerosis.

recommended that examinations be conducted as close as possible to a Doppler angle of 60 degrees. At this angle, errors in velocity calculations secondary to misreading of the Doppler angle are small as a percentage of the true velocity. When the Doppler angle approaches 70, these errors become much more significant. Small errors in determining the Doppler angle when the angle of insonation is less than 60 degrees have little overall impact on the calculation of the velocity of the moving red cells. Indeed, Doppler angles from 45 to 60 degrees are acceptable for most clinical studies. Most often an angle of 60 degrees can be easily obtained in carotid artery duplex examinations and, in line with traditional teaching, 60 degrees is chosen whenever possible as the Doppler angle in carotid duplex studies. In examination of other vessels, it may be much more difficult to adhere to a 60-degree angle.

As noted earlier, pulse Doppler both transmits and receives echoes with the same transducer. This dual function places limits on the frequencies that can be displayed in the spectral waveform. The maximum frequency that can be displayed is half the pulse-transmitting frequency or pulse-repetition frequency (PRF), and is known as the Nyquist limit. If frequencies are encountered that exceed the Nyquist limit, they are flipped and appear on the reverse flow side of the spectrum. This is termed “aliasing.” If aliasing is encountered, the PRF should be increased to increase the Nyquist limit. The PRF is adjusted by changing the scale displayed on the right side of the spectral waveform or by adjusting the baseline. If aliasing still occurs, the operator should consider switching to a lower-frequency transducer or to the use of a continuous wave Doppler. A continuous wave Doppler is not affected by aliasing.

Color Flow

A color flow image is produced by assigning color to Doppler shifts. Returning echoes that are not Doppler shifted are shown in grayscale. The net result is what appears to be color superimposed on a grayscale image. The hue and intensity of the color are determined by the direction and magnitude of the Doppler shifts. The technologist can adjust the color settings as desired. Varying shades of red and blue are used to distinguish flow away from or toward the transducer. By convention, most technologists assign red to arterial flow and blue to venous flow.

When the Doppler angle is 90 degrees, there is no Doppler shift. When this occurs, the assigned color is black and corresponds to the horizontal black bar serving as the baseline on the color scale that appears on the right side of a color flow image (Fig. 86.1). Aliasing can be readily recognized on a color flow image as a mosaic pattern or as a transition from red to blue or blue to red without an intervening black line. In areas of actual reverse flow, the blue and red colors are separated by a black border. Just as with pulsed Doppler, color aliasing can be reduced by increasing the PRF. This is often quite important,

as an extensive mosaic pattern can obscure clear visualization of a stenotic site.

Power Doppler is a variant of color Doppler. Power Doppler, however, assigns no direction of flow to the color image and velocity information is not calculated. Any detected Doppler shift is colorized without consideration of the direction of the Doppler shift or the magnitude of the Doppler shift. It is therefore not subject to aliasing or affected by Doppler angle. Its principal utility lies in the ability to detect blood moving at very low velocity and in outlining the course of tortuous vessels. It can be useful in detecting flow in small distal veins and flow in arteries distal to a very high-grade stenosis.

It is tempting to try and directly estimate the severity of a stenosis from the color flow image. It is generally agreed, however, that such estimates are probably less accurate than measurements of stenosis derived from spectral analysis. Color serves primarily as a guide in locating the vessels and selecting specific sites for examination with the pulse Doppler. The absence of color can indicate extensive mural calcification and difficulty in obtaining a pulse Doppler waveform.

CAROTID AND VERTEBRAL ARTERIES

Historically, the vascular laboratory began with assessing internal carotid artery (ICA) stenosis. Duplex diagnosis of ICA stenosis, and arterial stenoses in general, is based on duplex ultrasound and focuses on three areas, the prestenotic region, the stenosis itself, and the poststenotic region. Detecting carotid stenosis involves a combination of spectral analysis, color and grayscale imaging, and, in selected cases, power Doppler. The primary interest is in the detection of increased flow velocities within the area of suspected stenosis and therefore, in most cases, spectral analysis dominates in the detection of carotid stenosis. The exception is in distinguishing ICA occlusion from a very high-grade stenosis where color flow or power Doppler flow can identify very low flow in the area of the stenosis or distal to the stenosis that may not be detected by pulse Doppler.

In all cases, the pulsed Doppler and color flow findings should be cross-checked for concordance. If there is disagreement between the impression obtained with the color and pulsed Doppler examinations (i.e., color Doppler suggests high-grade stenosis but velocities are only moderately elevated), the findings of both should be reviewed to resolve the discrepancy.

COMMON CAROTID ARTERY WAVEFORMS

In the majority of cases, carotid stenosis or occlusion occurs in the proximal ICA at or just beyond the carotid bifurcation. A

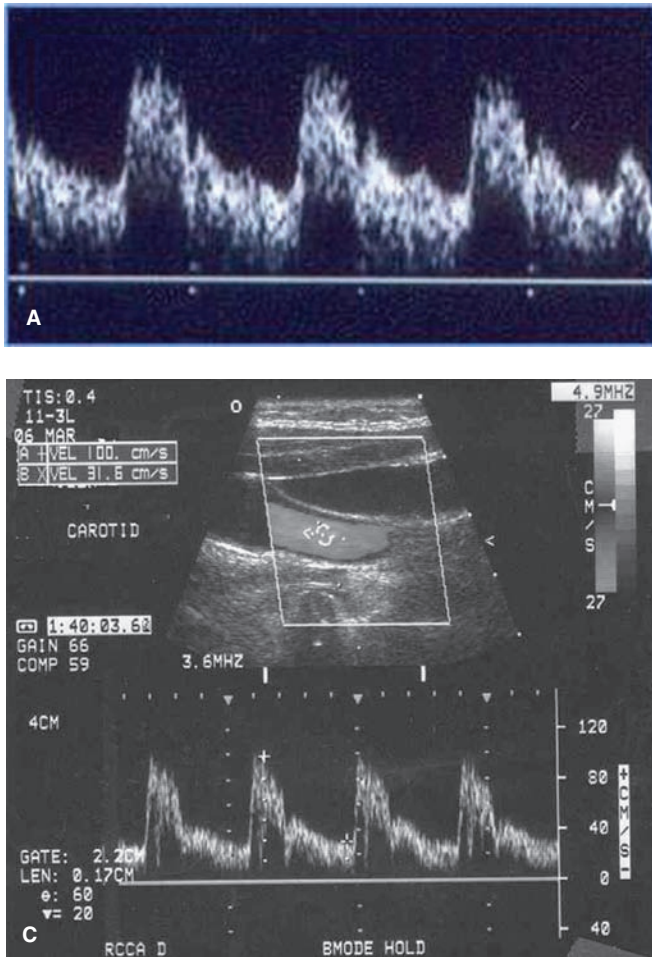

FIGURE 86.2. A normal internal carotid artery (ICA) waveform has low resistance; therefore, flow is relatively high at the end of diastole (A). The external carotid artery (ECA) supplies primarily the scalp and face, a higher-resistance circulation, and therefore end-diastolic flow is lower (B). Normally, 80% of common carotid artery (CCA) flow is directed to the ICA. Normal CCA end-diastolic flow is therefore generally well above baseline (C) and more closely resembles an ICA waveform.

normal internal carotid artery waveform reflects the low resistance of the cerebral circulation with high flow at the end of the diastolic component of the waveform (Fig. 86.2A). The external carotid artery (ECA) supplies the relatively higher-resistance circulation of the scalp and face and therefore has a low end-diastolic flow component (Fig. 86.2B). The common carotid artery waveform reflects the fact that normally 80% of common carotid artery (CCA) flow is directed to the ICA. CCA end-diastolic flow is therefore generally well above baseline and exceeds ECA diastolic flow (Fig. 86.2C). In the presence of a very high-grade ICA stenosis or ICA occlusion, outflow is primarily through the higher-resistance external carotid circulation. The CCA waveform then takes on the high flow resistance characteristics of an ECA, with flow to zero, or nearly zero, in end diastole¹ (Fig. 86.3). In addition, the peak systolic velocity (PSV) and the overall flow velocity may be substantially lower than normal due to reduced carotid artery flow. By observing these changes in the CCA, one can reliably predict the presence of high-grade stenosis or occlusion of the ICA.

The CCA contralateral to an ICA stenosis or occlusion may demonstrate an increased flow velocity with particular elevation of the velocity at the end of diastole, so-called end-diastolic velocity (EDV). These changes represent a compensatory increase in blood flow volume in the nonobstructed ICA in response to reduced contribution to cerebral perfusion from the opposite carotid artery. This compensatory hemodynamic change can be substantial and stenosis-related flow velocities may be artificially elevated on the side with compensatory high-volume flow.²

In the presence of a significant stenosis at the origin of a CCA or the innominate artery, the ipsilateral CCA waveform may be dampened, with low overall PSVs and EDVs and a

slower rise to peak systole when compared with the contralateral CCA waveform (Fig. 86.4). The CCA flow changes seen with proximal stenosis are also important in the diagnosis of ICA stenosis because the overall reduction in flow velocity may artificially lower velocities in an ipsilateral ICA stenosis, leading to underestimation of the severity of ICA stenosis. In some cases of proximal CCA or innominate artery stenosis, the ipsilateral CCA waveform may exhibit poststenotic turbulence low in the neck, representing disturbed flow distal to the more proximal stenosis.

FIGURE 86.3. Common carotid artery waveform from a patient with an internal carotid artery occlusion. There is essentially no end-diastolic flow, indicating that flow in this common carotid artery is now supplying the high-resistance circulation of the external carotid artery.

FIGURE 86.4. Common carotid artery (CCA) waveform distal to a more proximal high-grade CCA stenosis. The systolic upstroke is delayed and the amplitude of the waveform depressed, reflecting the presence of the proximal lesion. Diastolic flow is still well above baseline as the ipsilateral internal carotid artery was not significantly narrowed in this patient.

INTERNAL CAROTID ARTERY WAVEFORMS

As noted earlier, the normal ICA spectral waveform is indicative of high flow in a low-resistant circulation. The systolic upstroke is rapid, PSV is less than 125 cm/s, and flow is maintained throughout diastole³ (Fig. 86.2A). In the absence of plaque there is generally a clear spectral window under the outline of the spectral waveform, as there is little turbulent flow. The presence of color shifts, indicating high-velocity flow, and color mosaics, indicating poststenotic turbulence, aids in selecting potential areas for examination with the pulsed Doppler.

Hemodynamic quantification of the severity of ICA stenosis is primarily achieved by analysis of Doppler spectral waveforms and measurements of peak systolic and end-diastolic velocity or comparison of peak systolic velocities in the ICA to those in the CCA just proximal to the carotid bifurcation, the ICA/CCA ratio. As a stenosis develops, the PSV first becomes elevated. PSV is the principal measure of stenosis severity. EDV lags behind, relatively speaking, as stenosis severity progresses but rises rapidly as the stenosis becomes severe (diameter reductions of $\geq 60\%$). Thus, elevation of EDV is a good marker for high-grade stenosis⁴ (Fig. 86.5). The ICA/CCA ratio is also a very important measure of stenosis severity.⁵ Because it is a ratio, it compensates for abnormally high and low flow states that may skew the PSV and EDV upward or downward.

To accurately measure flow velocity, the sample volume must be placed within the area of greatest stenosis. Color flow imaging has demonstrated that the orientation of the stenotic jet within a stenosis is frequently not along the longitudinal axis of the vessel. This finding has resulted in controversy with regard to the proper technique of obtaining velocity waveforms at sites of stenosis. In areas of mild to moderate stenosis, use of a Doppler angle of 60 degrees to the long axis of the vessel is recommended. However, in areas of more severe stenosis and/or wall abnormalities, the Doppler angle of 60 degrees should be defined by the long axis of the stenotic flow jet, as demonstrated by color flow.

FIGURE 86.5. Internal carotid artery (ICA) waveform from the site of a greater than 80% ICA stenosis. Both peak systolic and end-diastolic velocities are very elevated.

The sample volume size should be kept as small as possible, usually 1.5 mm, to detect discreet changes in flow velocity. This is important as the highest velocities may be localized to a small area in the flow stream that emanate from the stenosis. A large sample volume that incorporates flow from many points within the vessel in the generation of the spectral waveform may give the false impression of disturbed flow, potentially leading to the misdiagnosis of moderate disease in an otherwise normal vessel. In practice, the sonographer, having identified the stenosis, gently moves a small sample volume around until the point of highest velocity is found.

Damping of spectral Doppler waveforms may be seen in the region distal to the carotid stenosis when the lesion is severe enough to be flow reducing. The most common abnormality seen distal to a carotid stenosis is spectral broadening caused by disturbed blood flow or frank turbulence. At best, poststenotic flow disturbance is a qualitative measure of arterial stenosis; nevertheless, its detection is important. With proper gain settings “fill-in” of the Doppler spectral waveform generally indicates the presence of carotid stenosis with diameter reduction of at least 50%. However, this level of disturbed flow occasionally can be seen with nonstenotic disease. Diagnostically, the most significant poststenotic flow disturbance produces a simultaneous forward and reverse spectral Doppler signal, accompanied by poor definition of the upper spectral border. Such disturbed flow implies the presence of severe carotid stenosis. Severely disturbed flow distal to a highly calcified plaque may be the only substantial evidence for the presence of clinically significant stenosis if calcification prevents direct insonation of the stenosis.

Vertebral Artery

On rare occasions, a stenosis may be found in the cervical portion of the vertebral artery associated with cervical osteoarthritis. However, the origin of the vertebral artery from the subclavian artery is by far the most common site of disease in the vertebral artery. The vertebral artery origin lies deep in

FIGURE 86.6. Color flow image of a vertebral artery. The Doppler cannot penetrate the vertebral bodies; therefore, there is no Doppler shift and no color where the artery passes through the vertebral foramen.

the base of the neck and may be difficult to access. Mean vertebral artery diameter is about 4 mm but the vertebral arteries are frequently asymmetric in size, with one, most commonly the left, being larger than the other.

The vertebral artery is most commonly interrogated with ultrasound further distally in the neck, from an anteroposterior window, as it threads through the transverse processes of the cervical spine. The vertebral bodies serve as a reference to ensure the vertebral artery is actually under examination (Fig. 86.6). The artery is usually seen deeper but adjacent to the vertebral vein. Color Doppler is helpful to locate the vessel. A spectral waveform from the vertebral artery in the mid-neck provides information about direction of flow, waveform shape, and velocity but does not rule out disease at the origin. The normal vertebral artery waveform is similar to that of the ICA with normal PSVs reported to be 20 to 40 cm/s.⁶ Velocities up to 80 cm/s are, however, frequently seen without apparent clinical importance and may represent collateral flow through a dominant vertebral artery, or a small but disease-free vertebral artery. Evaluation of disturbed flow distally may help determine which elevated velocities are associated with a vertebral artery stenosis and which are not. Velocity patterns are usually similar in the two vertebral arteries, but systolic and diastolic velocities may differ if vertebral artery diameters are asymmetric. For this reason, if there is concern for stenosis based on an elevated peak systolic velocity in a vertebral artery, recording of vertebral artery diameters is important.

Flow in the vertebral artery is normally antegrade with a rapid upstroke and continuous diastolic flow. In cases of anatomic subclavian steal, color flow provides an important initial clue to the diagnosis as flow in the artery will be retrograde in the same direction as the vein (Fig. 86.7). Spectral Doppler must still be used to verify arterial flow and will demonstrate reverse or bidirectional flow in cases of subclavian steal.

External Carotid Artery

The ECA is smaller in diameter than the ICA at the level of the carotid bulb but similar in diameter beyond the bulb. It has little clinical significance in most cases but can serve as an important source of collateral flow to the brain in cases of ICA very high-grade stenosis or occlusion. The ECA may also serve in such cases as a conduit for emboli to the brain, so-called carotid stump syndrome.⁷

FIGURE 86.7. This patient has reverse flow in the vertebral artery (systolic flow below the baseline), indicating the presence of a high-grade ipsilateral subclavian artery or innominate artery stenosis, so-called subclavian steal syndrome. In the absence of symptoms this finding is of uncertain significance.

The ECA waveform has a sharp upstroke, a prominent dicrotic wave in late systole or early diastole, and velocity that is near or at the zero baseline in end diastole. The PSV of the ECA is normally higher than the ICA. The ECA may adopt the characteristics of the ICA in end diastole as the resistance in the face and scalp decreases with temperature change and/or in the presence of disease.

CLASSIFYING CAROTID STENOSIS

Duplex criteria for quantifying carotid artery stenosis were developed by comparing duplex-derived spectral waveforms and contrast arteriograms. Duplex-derived categories of stenosis are relatively broad. Sensitivities and specificities for spectral analysis of duplex-derived waveforms for detecting an ICA stenosis of greater than 50% to 99% are between 90% and 95%. There are numerous spectral criteria for classifying ICA stenosis. Some focus on categories of stenosis, while others focus on threshold levels of stenosis.

One of the most widely accepted classification schemes for categories for ICA stenosis was developed at the University of Washington under the direction of Dr. Eugene Strandness. These criteria were useful in the study of the natural history of carotid atherosclerosis and in clinical practice. In the University of Washington system, velocity waveform analysis and spectral criteria were used to classify ICA angiographic stenosis as normal; 1% to 15%, 16% to 49%, 50% to 79%, or 80% to 99% stenosis; and occlusion. Prospective validation of these criteria has demonstrated an overall agreement of 82% with contrast angiography. The ability of the criteria to detect carotid disease is 99% sensitive and the ability of the criteria to recognize normal arteries is 84% specific.³

Criteria for detecting carotid artery stenosis scanning have undergone reevaluation to remain relevant to current clinical practice. This reevaluation was stimulated by the randomized trials testing the efficacy of carotid endarterectomy (CEA) that took place over the last two decades (Table 86.1).⁸⁻¹² These trials have had a profound impact on validating the indications for CEA in patients with carotid bifurcation atherosclerosis. The trials identified significant benefit, in terms of stroke reduction, for CEA in patients with specific levels of ICA

TABLE 86.1**MAJOR RANDOMIZED TRIALS ASSESSING EFFICACY OF CAROTID ENDARTERECTOMY**

Symptomatic stenosis

Asymptomatic stenosis

Asymptomatic Carotid Atherosclerosis Study (ACAS)¹¹Asymptomatic Carotid Surgery Trial (ACST)¹²

stenosis. In particular, patients with symptomatic ICA stenosis greater than 70% to 99% had dramatic benefit from CEA, while patients with symptomatic ICA stenosis between 50% and 69% and patients with asymptomatic ICA stenosis between 60% and 99% also benefited, albeit to a lesser extent, from CEA.

In the North American trials of CEA, ICA stenosis was calculated from arteriograms by comparing the diameter of the minimal residual lumen to the diameter of the distal cervical ICA.¹³ The University of Washington duplex criteria for categories of stenosis preexisted the endarterectomy trials and were developed comparing the diameter of the residual ICA lumen at its narrowest point with an estimate of the diameter of the ICA bulb if it were free of atherosclerosis. Because the bulb has a greater diameter than the distal ICA, the two methods of measurement do not give the same calculated percentage of angiographic stenosis for the same lesion. Calculations of angiographic stenosis using the distal ICA as the reference vessel result in lower calculated stenosis percentages than calculations using the bulb as the reference site. This effect is particularly striking for modest lesions.

In a review of 1,001 internal carotid angiograms, 34% of the ICAs were classified as stenosis of 70% to 99% using the ICA bulb as the reference vessel. In contrast, when the distal cervical ICA was used as the reference site, only 16% of the ICAs were classified as 70% to 99% stenosis.¹⁴ More than 99% of distal ICA-based calculations of stenosis were less than bulb-based calculations. Thus, the duplex stenosis criteria using the bulb as the reference vessel are not and were not directly applicable to the results of the clinical trials.

CURRENT CRITERIA FOR INTERNAL CAROTID ARTERY STENOSIS

Since the randomized CEA trials were completed, additional duplex criteria were developed comparing duplex scans to angiographic ICA stenosis using the distal ICA as the reference vessel in calculating angiographic stenosis. Such criteria are considered more useful by many in selection of patients for carotid intervention because they are directly applicable to the threshold levels of carotid stenosis addressed in the CEA trials.

The initial studies addressing the issue of duplex criteria relevant to the CEA trials were performed at the Oregon Health & Science University (OHSU)^{5,15} with subsequent publications from many different institutions, most of which proposed different criteria for the identification of the clinically relevant threshold levels of ICA stenosis.^{16–21}

Recognizing that duplex criteria from different centers differed for the threshold levels of angiographic stenosis determined by the CEA trials, a panel of authorities from a variety

of medical specialties assembled to review the carotid ultrasound literature. The panel developed a consensus regarding the key components of the carotid ultrasound examination and reasonable criteria for stratification of ICA stenosis.²²

The consensus committee recommended that all carotid examinations be performed with grayscale imaging, color Doppler, and spectral Doppler. Examinations should be performed by a credentialed vascular technologist in accordance with the standards of one of the accrediting bodies. Doppler waveforms should be measured with an insonation angle as close to 60 degrees as possible but not exceeding 60 degrees, and the sample volumes should be placed within the area of maximal stenosis. The panelists recommended the consistent use of relatively broad diagnostic strata to estimate the degree of ICA stenosis. The panel also concluded that Doppler is relatively inaccurate for subcategorizing ICA stenoses less than 50% and recommended that these lesions be reported under a single category as less than 50% stenosis and that the subcategories for minor degrees of stenosis not be used.

The consensus panel noted that PSV is easy to obtain. However, data suggest that reproducibility of PSV, even among experienced vascular technologists, has sufficient problems that PSVs should not be used as a continuous variable in clinical carotid duplex scanning. Even so, the degree of stenosis estimated by ICA PSV and the degree of narrowing of the ICA lumen seen on grayscale and color Doppler should correlate with PSV as the primary parameters for determining ICA stenosis. Additional parameters such as the ICA/CCA PSV ratio and ICA EDV are secondary parameters and should be employed as internal checks. They are especially useful when ICA PSV may not be representative of the extent of disease. After their discussions the consensus panel recommended criteria, stratifying ICA stenosis into specific categories relevant to the CEA trials (Table 86.2). These criteria have not been subjected to retrospective or prospective evaluation and do not represent the results of any one laboratory or study. They are not meant to serve as a substitute for continuous quality assurance in individual laboratories.

BILATERAL HIGH-GRADE INTERNAL CAROTID ARTERY STENOSIS

Doppler-derived flow velocities from the ICA opposite an ICA occlusion or high-grade stenosis may suggest a higher degree of narrowing than is observed angiographically.² This is likely due to compensatory flow. Duplex scan overestimation of stenosis is more common in less severe categories of stenosis than in higher-severity categories.²³

STENTED CAROTID ARTERIES

Carotid artery stenosis is increasingly treated with an intraluminal stent. However, ultrasound criteria developed for native ICAs are likely not applicable to stented carotid arteries, especially to more modest lesions in the stented arteries. With rare exceptions, the number of patients in studies of stented carotid arteries that have actually had severe in-stent restenosis is small. No study has correlated the degree of stenosis or increase in ICA velocities within a stented carotid artery with clinical symptoms or outcomes. Studies have also not evaluated the effect of the stented carotid artery on the opposite nonstented artery. Currently, it appears that for more modest lesions, higher PSVs (i.e., >125 cm/s) will be needed to identify a greater than 50% stenosis in a stented ICA, whereas criteria to detect high-grade stenosis in native ICAs still work reasonably well to identify high-grade stenosis in stented ICAs.²⁴

TABLE 86.2**CONSENSUS PANEL RECOMMENDATIONS FOR CLASSIFICATION OF INTERNAL CAROTID ARTERY STENOSIS**

Normal: The ICA PSV is <125 cm/s and there is no visible plaque or intimal thickening. Normal arteries should also have an ICA/CCA PSV ratio of <2.0 and ICA EDV of <40 cm/s.

ICA stenosis $<50\%$ is present when the ICA PSV is <125 cm/s and there is visible plaque or intimal thickening. Such arteries should also have an ICA/CCA PSV ratio of <2.0 and an ICA EDV of <40 cm/s.

ICA stenosis of 50% – 69% is present when the ICA PSV is 125 cm/s to 230 cm/s and there is visible plaque. Such arteries should also have an ICA/CCA PSV ratio of 2.0 – 4.0 and an ICA EDV of 40 – 100 cm/s.

ICA stenosis $\geq 70\%$ – 99% but less than near occlusion is present when the ICA PSV is >230 cm/s and there is visible plaque with lumen narrowing on grayscale and color Doppler imaging. The higher the PSV, the more likely (higher positive predictive value) it is to have severe disease. Such stenoses should also have an ICA/CCA PSV ratio of >4.0 and an ICA EDV of >100 cm/s.

Near occlusion of the ICA: The velocity parameters may not apply. “Preocclusive” lesions may be associated with high, low, or undetectable velocity measurements. The diagnosis of near occlusion is therefore established primarily by demonstration of a markedly narrowed lumen with color Doppler. In some near-occlusive lesions, color Doppler can distinguish between near occlusion and occlusion by demonstrating a thin wispy of color traversing the lesion.

Occlusion: There is no detectable patent lumen on grayscale imaging and no flow with spectral, color, and power Doppler. Near-occlusive lesions may be misdiagnosed as occlusions when only grayscale ultrasound and spectral Doppler are used.

CCA, common carotid artery; ICA, internal carotid artery; EDV, end-diastolic volume; PSV, peak systolic velocity.

From Grant EG, Benson CB, Moneta GL, et al. Carotid artery stenosis: gray-scale and Doppler US diagnosis—Society of Radiologists in Ultrasound Consensus Conference. *Radiology* 2003; 229:340–346.

COMMON CAROTID ARTERY AND EXTERNAL CAROTID ARTERY STENOSIS

Criteria used for classifying disease in the ICA have not been tested for application to the ECA or the CCA. However, as with the ICA, relative degrees of stenosis may be determined by the presence of plaque with B-mode imaging, aberration in color flow on duplex examination, spectral broadening, and increases in PSV. Although not specifically tested, stenosis of more than 50% can be inferred by the presence of a focally increased PSV followed by poststenotic turbulence. As noted earlier, the CCA waveform normally has attributes of the ICA and ECA. The CCA will take on the quality of the “normal” vessel (ICA or ECA) when the other is occluded. If there is a proximal CCA (or innominate artery) high-grade stenosis or occlusion, the ipsilateral CCA Doppler flow quality will be dampened with low PSVs, as compared with the contralateral side. Poststenotic turbulence also may be seen. There are no widely employed validated criteria to give a diameter reduction for stenosis in the CCA or ECA. Stenosis of more than 50% is inferred by a PSV of more than 125 cm/s associated with poststenotic turbulence.

LOWER EXTREMITY ARTERIAL DISEASE

- 4 The noninvasive vascular laboratory, in combination with the history and physical examination, has a critical role in providing objective diagnosis of lower extremity arterial occlusive disease in asymptomatic patients, those with intermittent claudication, and those with critical arterial insufficiency. Both plethysmographic and ultrasound techniques are used in the evaluation of peripheral arterial disease.

In many patients the clinical history and physical examination is all that is necessary to establish a diagnosis of intermittent claudication (IC). Almost all patients with IC have diminished or absent lower extremity pulses. However, palpation of pulses is subjective and poorly reproducible. Therefore, in almost all cases, the pulse examination in a patient suspected of having arterial disease should be supplemented with objective testing in the noninvasive vascular laboratory. On occasion, a patient will give a history suggesting IC yet have what appear to be normal resting pedal pulses. Exercise testing with postexercise Doppler-measured ankle-brachial systolic blood pressure ratios is crucial to confirm the diagnosis of IC secondary to arterial disease (see later).

Many patients with peripheral arterial disease (PAD) have atypical leg symptoms or are asymptomatic. Such patients have similar increased risk of cardiovascular death as patients with typical IC symptoms. The recognition of these patients has resulted in an increased interest in screening for the presence of PAD in patients with atypical leg symptoms and/or atherosclerotic risk factors.

Patients with exercise-induced lower extremity and/or buttock pain should be asked the location of the pain, its relationship to walking, severity and duration of symptoms, and symptom progression over time. Only exercise-induced muscular pain of the calf, thigh, or buttock, relieved within a few minutes of rest and reproduced by additional walking, can be reliably improved by lower extremity arterial revascularization. There are no data on the response of atypical leg symptoms to revascularization in patients with evidence of PAD.

Ischemic pain is a clinical diagnosis. It is suspected when a patient complains of pain and/or numbness in the forefoot, toes, or instep at rest. In such patients the vascular laboratory can objectively confirm and quantify the magnitude of arterial insufficiency.

PLETHYSMOGRAPHIC TECHNIQUES

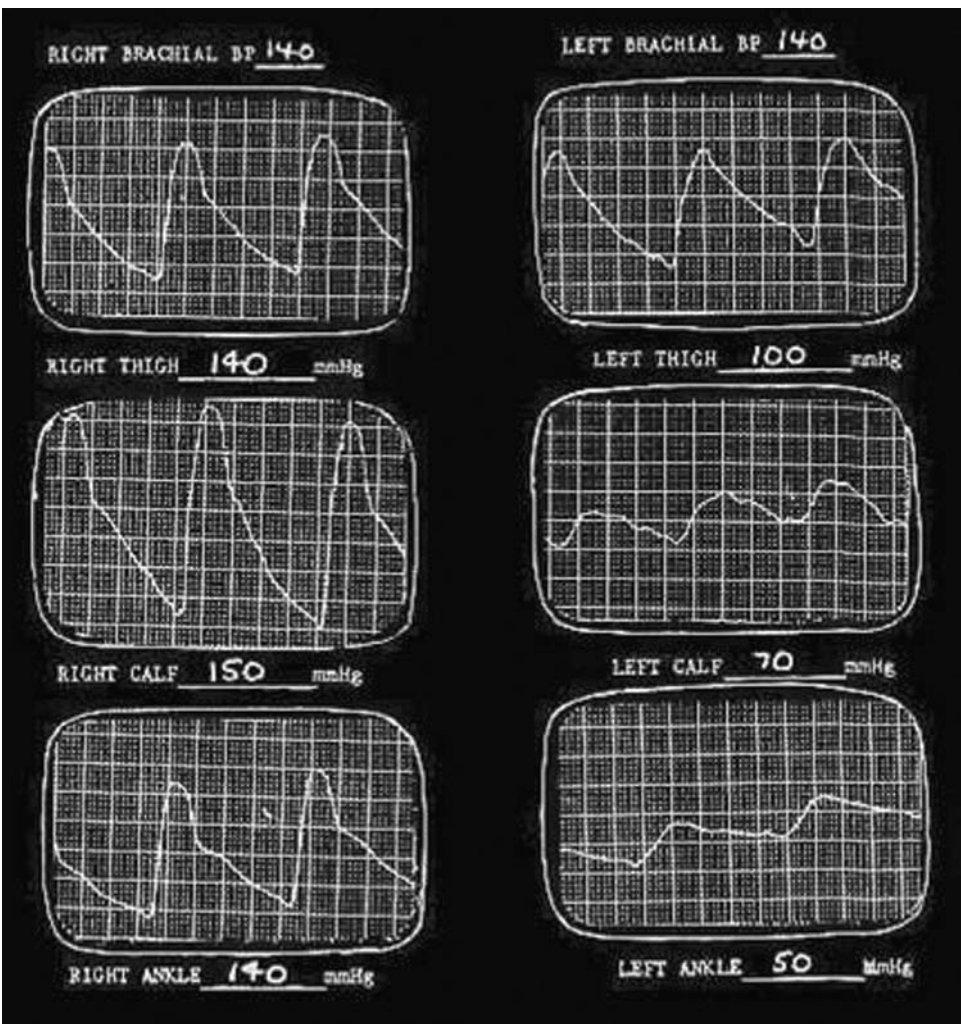

Volume Flow

Calf or foot blood flow can be recorded with a mercury-in-silastic strain gauge. Electrical resistance of the mercury column depends on the length of the column and changes in electrical resistance reflecting. Changes in the volume of the extremity, are based on detection of minute changes in the length of the column. However, neither calf nor foot blood flow at rest differs between normal subjects and patients with even rather severe IC.²⁵ Hyperemic volume flow is often lower in patients with occlusive disease, but such testing can be quite painful for the patient.²⁶ Measurements of volume flow therefore are not very useful in the evaluation of lower extremity ischemia.

Pulse Volume Recordings

Air plethysmography can be used to display pulse volume waveforms.²⁷ Pulsed volume recordings are obtained with

FIGURE 86.8. The pulse volume recordings (PVRs) are normal on the right with rapid upstrokes and a dirotic notch on the downstroke of the waveform. PVRs on the left are abnormal with loss of amplitude, delay in rise of the waveform, and absence of the dirotic notch.

partially inflated blood pressure cuffs that detect volume changes sequentially down a limb. Volume changes beneath the cuffs resulting from the pulse wave result in small pressure changes within the cuffs. These changes are displayed as arterial waveforms with the use of appropriate transducers. A normal pulse volume waveform has a sharp systolic upstroke and peak, as well as a prominent dirotic notch on the downward portion of the curve. With increasing proximal arterial occlusion, the dirotic notch is lost. The peak of the pulse wave becomes rounded and there is loss of amplitude of the wave as disease is more severe. With even more severe disease there are nearly equal upstroke and downstroke times, and in very severe proximal disease the pulse wave is absent²⁸ (Fig. 86.8). Evaluation of pulse volume waveforms is qualitative based on the shape of the curve, the presence or absence of the dirotic notch, and the amplitude of the waveform.²⁹ Lack of quantitative data limits the utility of pulse volume recordings. More quantitative data for the evaluation of lower extremity arterial disease are available using ultrasound-based techniques.

ULTRASOUND TECHNIQUES

Ankle-Brachial Index

5 The ankle-brachial index (ABI) is a very useful measure of overall lower extremity perfusion. The test is performed with the patient supine and having rested for a few minutes. A pneumatic pressure cuff is placed just above the ankle and inflated to suprasystolic levels. A continuous wave Doppler

probe is positioned over the posterior tibial or dorsalis pedal artery distal to the cuff. The cuff is deflated and the pressure reading when the Doppler signal returns is recorded. The sequence is repeated for the other ankle artery and the values compared with the highest brachial artery systolic pressure, also obtained with the Doppler. For clinical purposes, the higher ipsilateral dorsal pedal or posterior tibial pressure is divided by the higher brachial artery systolic pressure, yielding an ABI for that lower extremity. The use of a ratio makes the test relatively independent of day-to-day variations in arterial blood pressure.

A normal ABI is 1.0 to 1.2, with progressively lower values corresponding to worsening arterial disease (Table 86.3). ABIs

TABLE 86.3

CORRELATION BETWEEN ANKLE-BRACHIAL INDEX (ABI) AND CLINICAL SEVERITY OF LOWER EXTREMITY ARTERIAL ISCHEMIA

■ ABI	■ CLINICAL STATUS
>1.3	Abnormal, significant arterial wall calcification
1.1 ± 0.1	Normal
0.6 ± 0.2	Intermittent claudication
0.3 ± 0.1	Ischemic rest pain
0.1 ± 0.1	Impending tissue necrosis

FIGURE 86.9. Placement of blood pressure cuffs for measurement of lower extremity segmental pressures using the four-cuff technique.

below normal indicate relative lower extremity arterial insufficiency and increased risk of cardiovascular death, with the risk increasing with the magnitude of depression of the ABI. This test has several limitations. Significant bilateral subclavian or axillary artery occlusive disease results in a falsely elevated ABI. Calcified tibial arteries that can occur with diabetes or renal failure may be inadequately compressed by the pressure cuff. This also results in a falsely elevated (suprasystolic) ankle pressure. An ABI greater than 1.4 should also be considered abnormal. Such patients have severe arterial disease and are also at increased risk of cardiovascular death. When the ABI may be falsely elevated, qualitative analysis of Doppler-derived analogue or plethysmographic waveforms or measurement of digital systolic pressures is a more appropriate indicator of the arterial status of the lower extremity. Other problems with the ABI include confusion with venous signals when the ankle arterial pressure is low or unmeasurable and relative insensitivity to certain patterns of progression of arterial disease. A tibial artery can occlude without a change in ABI if the remaining tibial vessels remain patent. High-grade stenosis may also progress to occlusion without a change in ABI.

Segmental Limb Pressures

Multiple pneumatic cuffs may be used along the lower extremity to determine the arterial blood pressure at each level (Fig. 86.9).

These segmental leg pressures are compared with the higher brachial artery systolic pressure, with other locations in the ipsilateral leg, and with the corresponding levels in the contralateral extremity. Three or four cuffs may be used. In the four-cuff technique cuffs are placed (a) as far proximal on the thigh as possible, (b) immediately above the knee, (c) just below the knee, and (d) just proximal to the ankle. Each cuff width should be 20% greater than the diameter of the limb at the point of application to avoid falsely elevated pressure readings induced by too narrow a cuff.³⁰ In the thigh, this would generally necessitate a single, wide, thigh cuff. Use of two cuffs above the knee, however, can permit assessment of inflow at or proximal to the common femoral artery with the proximal cuff and permit evaluation for the presence of superficial femoral artery disease with the distal thigh cuff. With two thigh cuffs the most proximal thigh cuff is often too narrow. An artificially elevated pressure in the proximal thigh is then expected. Therefore, the high-thigh index, comparing the proximal thigh pressure to the brachial pressure, is normally about 1.4 with the four-cuff technique and 1.0 to 1.1 with the three-cuff technique.

A hand-held Doppler is used to detect the most prominent Doppler signal at the ankle. Examination proceeds proximal to distal. First, the high-thigh cuff is inflated until the ankle Doppler signal is no longer audible. The cuff is then deflated and the pressure where there is return of the Doppler signal at the ankle is the high-thigh pressure. The above-knee, below-knee, and ankle pressures are similarly determined. If there is no audible ankle Doppler signal, the popliteal artery is insonated with the Doppler to determine high-thigh and above-knee pressures. Comparison of the pressures measured at each location permits an estimation of the location of occlusive lesions (Fig. 86.10).

There are limitations in the interpretation of segmental limb pressures. The high-thigh pressure is subject to particular interpretation difficulties. A diminished high-thigh pressure can reflect an occlusive lesion anywhere at or proximal to the common femoral artery bifurcation. Low high-thigh pressures therefore may reflect a pressure-reducing stenosis in the ipsilateral common or external iliac artery, a common femoral artery lesion, tandem pressure-reducing lesions in the profunda femoris and the proximal superficial femoral artery, or any combination of such lesions. The accuracy of segmental pressures is also affected by mural calcification resulting in artificially elevated pressures. Diminished proximal pressures may also mask gradients that exist further down the leg. Segmental pressures do not allow differentiation between short- and

FIGURE 86.10. Segmental pressures indicate the presence of a significant occlusive lesion at or proximal to the common femoral artery bifurcation on the right and a significant superficial femoral artery lesion on the left. See text for explanation.

long-segment occlusions or between occluded and patent, but highly stenotic, arteries.

Exercise Testing

Doppler-determined pressures can be combined with treadmill exercise testing in patients without a contraindication to exercise. After determination of resting supine ankle pressures and ABIs, the patient walks on a treadmill with a predetermined incline at a predetermined rate. The test continues for 5 minutes or until the patient is forced to stop. The type, time to onset, and location of symptoms are recorded. At completion of the test, the patient is immediately placed supine and absolute ankle pressures and ABIs determined.

In most patients exercise testing serves only to confirm a diagnosis of claudication. It is not required in a patient with classic symptoms of claudication, absent peripheral pulses, and a diminished ABI. In some cases exercise testing can document a physiologic response to revascularization or provide an objective assessment of the potential postoperative physiologic benefit.

Exercise testing is particularly useful in the patient with symptoms of claudication and who has palpable pedal pulses and a normal ABI. Patients with exercise-induced leg pain occurring on the basis of arterial insufficiency will show a decrease in the postexercise ABI. Exercise testing can also be used to document an ischemic response to exercise in patients with PAD and other conditions that may limit their ability to walk. Patients with COPD, arthritis, venous disease, and PAD are often more limited in their walking ability by these coexisting conditions than by their PAD. If the patients cannot complete a treadmill examination, but no ischemic pressure response to exercise occurs, it is highly unlikely their walking ability would be improved by a revascularization procedure.

The precise endpoints and techniques of exercise testing are controversial. Some laboratories exercise patients at low speeds with no inclination of the treadmill, while others utilize various inclines and graded increases in treadmill speed. Both initial and absolute claudication distances can be determined. Initial claudication distance is the point where the patient initially experiences claudication-type pain. The absolute claudication distance is where the patient can no longer continue to walk on the treadmill.

Criteria for a positive exercise test include a decrease in the ankle pressure of 20 mm Hg or 20%, a decrease in the ABI of 0.2 in the symptomatic extremity, or failure of the ankle pressure to return to baseline within 3 minutes of completing the treadmill portion of the examination. Because systemic pressure and therefore arm pressures, depending on workload, will increase with exercise, use of the ABI alone to indicate a positive exercise test is incorrect. The ABI decrease should be accompanied by an absolute pressure drop at the ankle.

Failure of the ankle pressure to drop with exercise along with failure of the ABI to decrease 20% with exercise, combined with a normal resting ABI, substantially rules out arterial insufficiency as the etiology of the patient's exercise-induced leg pain. An exception is the rare patient with buttock claudication secondary to isolated internal iliac disease.

Neurogenic claudication may be confused with arterial ischemia. Patients present with symptoms of exercise-induced leg or calf pain. Careful questioning, however, reveals atypical characteristics for vascular-induced exercise-associated pain. Such characteristics include occurrence of pain with standing, pain relief leaning forward, worsening with coughing, and prolonged time for pain to resolve following exercise. These patients have normal ankle pressures at rest that do not decrease with exercise despite onset of symptoms. Failure of the ankle pressures to decrease with exercise may also be a clue to the presence of other uncommon conditions, such as venous claudication and chronic exercise-induced compartment syndromes.

Doppler Analogue Waveform Analysis

Similar to plethysmographic waveforms, continuous wave Doppler waveforms may also be analyzed qualitatively. Normal lower extremity Doppler waveforms are described as triphasic with a sharp systolic upstroke and an end-systolic reverse flow component followed by low flow forward through diastole. The shape of the waveform changes with increasing severity of proximal obstruction. Initially, the reverse flow component is lost. As proximal stenosis increases, the rate of rise of the systolic upstroke is decreased, the amplitude of the waveform is diminished, and diastolic flow increases relative to systolic flow.

Continuous wave Doppler waveforms are generally used in conjunction with measurement of segmental Doppler pressures similar to the use of pulse volume recordings. Doppler waveform analysis can also be used to assess iliac artery inflow to the common femoral artery. An attenuated common femoral artery waveform indicates proximal disease.

Peripheral Artery Duplex Scanning

- 6 Arterial duplex scanning provides detailed anatomic and hemodynamic information from the infrarenal aorta to the distal tibial vessels that cannot be determined by indirect testing. Arterial duplex scanning has been prospectively compared with angiography to establish standard criteria for normal and diseased arteries.³¹ Sensitivity of duplex examination for detecting the presence of a hemodynamically important lesion (>50%) ranges from 89% at the iliac artery to 68% at the popliteal artery. Overall sensitivities for predicting interruption of patency are 90% for the anterior and posterior tibial arteries and 82% for the peroneal artery. The technique is versatile and does not appear to be influenced by the presence of previous operations or multilevel disease (Fig. 86.11).

Velocity Patterns and Classification of Percent Stenosis

Lower extremity waveforms from normal resting peripheral arteries are triphasic. End-diastolic flow is near zero, reflecting the high end-organ resistance associated with the peripheral circulation. Triphasic waveforms are maintained throughout the length of the lower extremity, but PSV decreases from the iliac to the tibial vessels. There is no significant difference in velocity measurements among the three tibial arteries in normal subjects.

Important changes in the velocity waveforms that signify disease include the absence of an end-systolic reverse flow component and elevation of the peak systolic velocity. A 50% reduction in arterial diameter (equivalent to a cross-sectional surface area reduction of 75%) is associated with a pressure drop across the lesion. The University of Washington criteria for classification of peripheral arterial stenoses is shown in Table 86.4.³²

A PSV ratio, comparing the velocity within the stenosis to the velocity just proximal to the stenosis, is also useful for grading degree of stenosis. PSV ratios are independent of changes in blood pressure, cardiac output, and vascular compliance. Typically, grading stenoses using the PSV ratio has been found to be highly reproducible.^{33,34} Fifty percent stenoses in lower extremity arteries correlate with a PSV ratio from 1.4 to 3.0.^{31,35-38} A velocity ratio of 2.0 is a reasonable compromise and is used by many vascular laboratories as indicative of a 50% peripheral arterial stenosis.

Lower extremity duplex scanning can serve as an alternative to contrast arteriography in the preoperative assessment of candidates for arterial intervention. In selected centers,

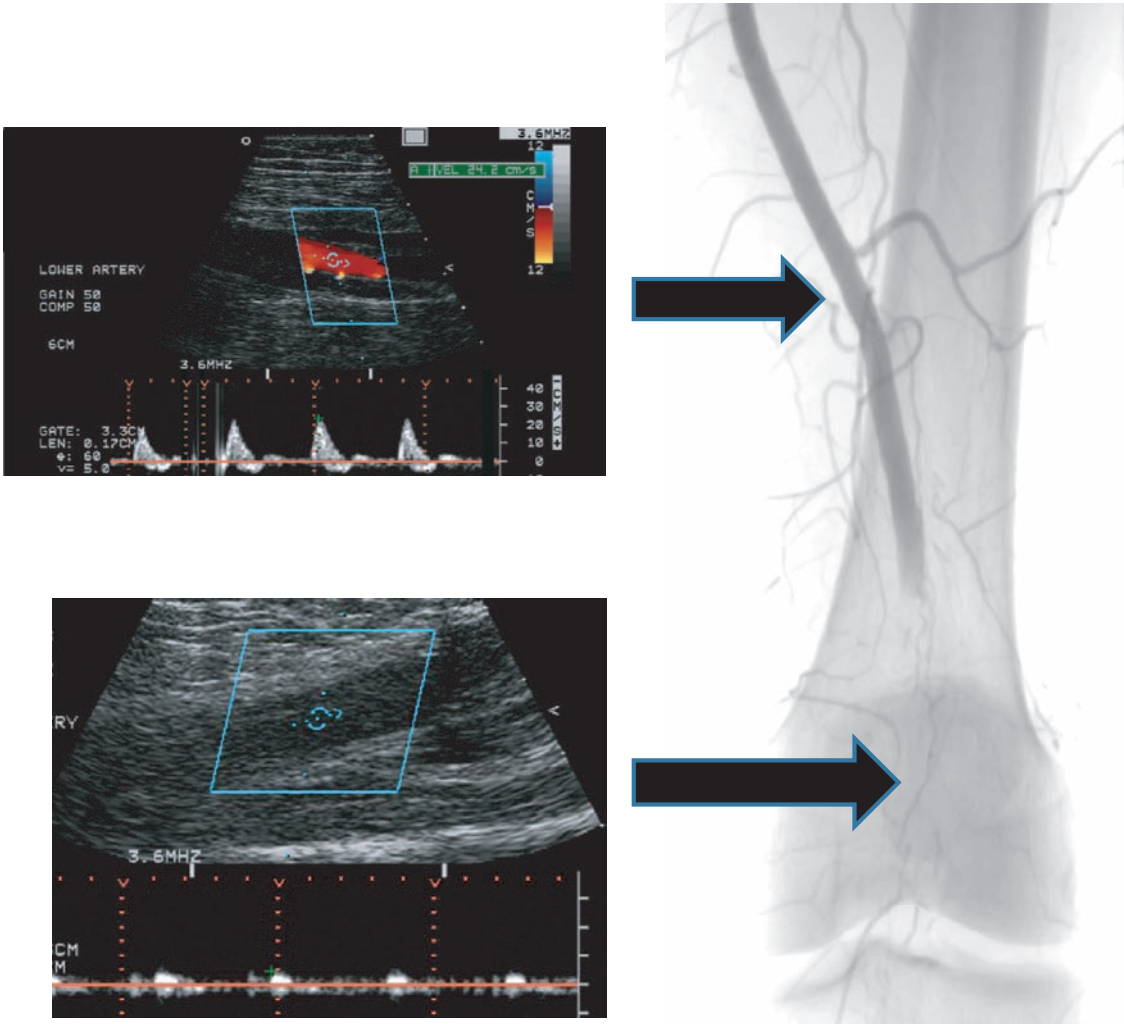

FIGURE 86.11. Duplex waveforms and a corresponding angiogram in a patient with acute lower extremity ischemia. Note the absence of ultrasound-detected flow in the area of the popliteal artery occlusion.

TABLE 86.4

UNIVERSITY OF WASHINGTON DUPLEX CRITERIA FOR DETERMINATION OF STENOSIS IN LOWER EXTREMITY ARTERIES

DEGREE OF STENOSIS (%)	DUPLEX ULTRASOUND CRITERIA
0	Normal waveform and velocities
1–19	Normal waveform and velocities with spectral broadening
20–49	Marked spectral broadening, 30% increase in PSV
50–99	Marked spectral broadening, 100% increase in PSV Loss of reverse-flow component of waveform
Occluded	No detectable flow signal in well-visualized artery

PSV, peak systolic velocity.

successful lower extremity revascularization either by open arterial bypass grafting or with catheter-based techniques has been reported using only arterial duplex in a high percentage of cases.^{39–41} The limiting factor with preoperative arterial duplex is the ability to accurately identify the best site for the distal anastomosis of a bypass graft, especially when the distal anastomotic site is below the knee.⁴²

The role of duplex ultrasound scanning in the surveillance of lower extremity vein grafts has been well documented (Figs. 86.12 and 86.13). Detection and repair of graft-threatening stenoses detected by duplex scanning appear to improve secondary graft patency.^{43–46} Twenty to thirty percent of vein grafts will develop a severe enough stenosis that revision is recommended.⁴⁷ Approximately 80% of these graft stenoses develop in the first postoperative year. However, graft-threatening lesions can develop at any time. Surveillance is therefore generally recommended for the life of the graft. A widely utilized protocol for vein graft duplex surveillance is every 3 months for the first year and every 6 months thereafter. The examination involves insonation of the proximal inflow artery, proximal anastomosis, midgraft, distal anastomosis, and distal outflow artery. A PSV ratio of 4, or a PSV above 300 cm/s, indicates a critical graft stenosis, and repair of the lesion by open or catheter-based techniques should be considered.⁴⁸ If

FIGURE 86.12. A peak systolic velocity of almost 300 cm/s is worrisome for the presence of a more than 50% stenosis at the origin of the patient's femoral popliteal bypass.

the PSV ratio is between 2 and 4, the patient should be reevaluated in 3 months with a duplex examination.

Upper Extremity Arterial Evaluation

Upper extremity arterial disease is a small but important component of vascular surgical practice. Both ultrasound and plethysmographic techniques are important in the evaluation of upper extremity arterial disease.

SEGMENTAL ARM PRESSURES

Upper extremity segmental pressures are obtained by measuring blood pressure with pneumatic cuffs above the elbow, below the elbow, and above the wrist while insonating the radial or ulnar artery at the wrist using a continuous wave

FIGURE 86.13. The peak systolic velocity in this patient's lower extremity bypass graft is normal and the waveform exhibits normal triphasic flow. There is no evidence of stenosis in the graft at this point. The graft must, however, be examined along the entire length of the graft as stenoses can exist distally with normal proximal waveforms and velocity measurements.

Doppler. Doppler-derived or plethysmographic waveforms can also be recorded at the different levels. Abnormal waveforms or pressures will help diagnose arterial disease proximal to the wrist.

A 12-cm blood pressure cuff is usually sufficient for measuring the brachial artery pressure, while a 10-cm blood pressure cuff is used at the wrist to measure the systolic pressure from the radial and ulnar arteries. A systolic pressure measurement is taken from the upper arm (brachial artery) and at the wrist (radial and ulnar arteries). Normally, there is not a recordable gradient between any of these sites and a normal wrist/brachial blood pressure ratio is 1.0. If there is a blood pressure difference between the two arms of more than 15 mm Hg, it is likely that there is a stenosis or occlusion somewhere on the side of the lower pressure. Abnormal waveforms and decreased pressures at the above-elbow cuff site indicate axillary, subclavian, or brachiocephalic arterial occlusive disease. Similarly, abnormalities at the below-elbow and above-wrist sites indicate brachial and proximal ulnar/radial arterial occlusive disease, respectively. If there is a blood pressure difference between levels, or between the radial and ulnar arteries, of more than 15 mm Hg, it is likely due to a stenosis or occlusion (Fig. 86.14).

DIGITAL PRESSURES AND PLETHYSMOGRAPHY

- 7 Digital pressure measurements and digital plethysmography are extremely useful in the diagnosis of upper extremity arterial disease and can be as accurate as arteriography in assessing patients with hand ischemia.⁴⁹ Either photoplethysmography (PPG) or strain-gauge plethysmography can be used to measure digital blood pressure and to obtain pulse waveforms. PPG is preferred because the equipment is easier to use and more durable. An additional advantage of PPG is that it is possible to record the volume pulses from the tips of the digits. This may also be useful in documenting obstruction within the digit arteries themselves.

The photo cell is attached to the fingertip pulp with double-sided tape or small strain gauges are placed around the fingertip. One-inch (2.5 cm) blood pressure cuffs are placed around the proximal phalanx (Fig. 86.15). Waveforms are recorded using pulse tracings obtained at high speed to evaluate the shape of the waveform. Waveforms are normal if the upstroke time is less than 0.2 seconds (Fig. 86.16A, B). They may or may not have a dicrotic notch. An abnormal obstructive waveform will have a rounded peak, as opposed to the normal notched peak. Upstroke time is prolonged. The amplitude of the waveform is not important. Finger PPG waveforms are not quantitative. The amplitude of the waveform is dependent on the gain setting, not blood flow.

Patients with vasospasm will often have an abnormally shaped waveform termed a "peaked pulse," which is thought to represent abnormal elasticity and rebound of the palmar and digital vessels (Fig. 86.17).

Finger blood pressures are measured by inflating the cuffs placed at the base of the fingers. At reduced chart recorder speed the pulsations are recorded while the blood pressure cuffs are inflated. When digit pulsations are obliterated, the cuff is slowly deflated until the pulsation returns. The pressure reading at this point is recorded and represents the digital artery pressure.

It is extremely important to measure and record finger temperature before performing digital plethysmography and obtaining finger blood pressures. If the finger temperature is less than 28°C to 30°C, false-positive results may be obtained secondary to cold-induced vasospasm. It is recommended that hand and/or whole body warming be performed in patients with low finger temperatures. The technologist should record

FIGURE 86.14. Upper extremity segmental pressures and Doppler-derived waveforms. Pressures and waveforms are normal on the right but indicate the presence of radial artery occlusive disease and ulnar artery occlusion on the left. The normal axillary and subclavian artery waveforms on the left suggest the absence of significant occlusive disease proximally on the left. The study is compatible with embolization from a left subclavian artery aneurysm.

FIGURE 86.15. Digital blood pressure cuff and photoplethysmography sensor for measurement of digital artery blood pressures.

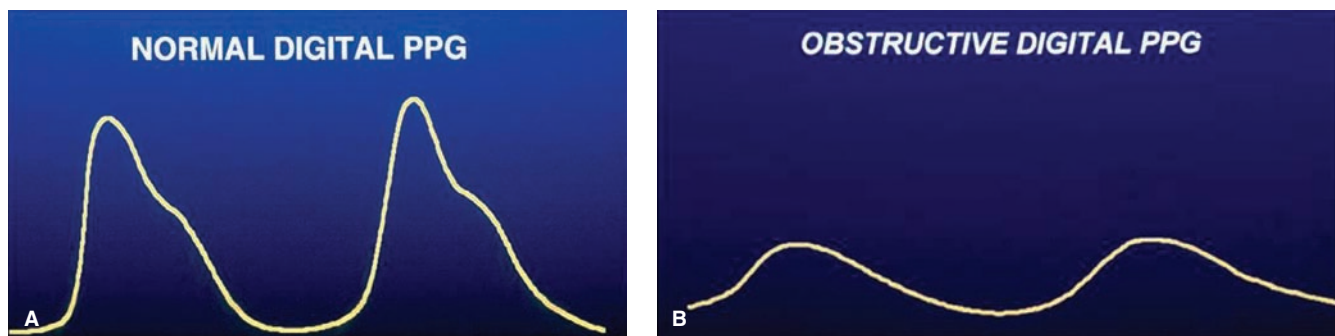

FIGURE 86.16. Normal (A) and obstructive (B) digital photoplethysmographic (PPG) waveforms. The normal waveform has a rapid upstroke and a sharp apex, while the obstructive waveform demonstrates a delayed upstroke and rounded apex.

FIGURE 86.17. A so-called peak pulse digital PPG waveform demonstrating a dicotic notch high on the systolic down-slope of the waveform. This type of waveform can be seen in patients with the purely vasospastic form of Raynaud's syndrome.

the finger temperatures to ensure the interpreting physician that chances of vasospasm have been minimized.

Digital blood pressure is normally within 20 to 30 mm Hg of brachial pressure. A ratio of finger systolic pressure to brachial systolic pressure of greater than 0.80 is normal but does not necessarily rule out digital artery occlusive disease. It is important to remember that there are occasional patients with very distal digital artery occlusive disease with normal finger pressures since the digital cuff is around the proximal phalanx. Also, occlusive disease in a single digital artery can be missed if the other digital artery in that finger is normally patent.

COLD CHALLENGE TESTING

The simplest cold intolerance test is to measure the digital temperature recovery time after immersion of the hand in ice water for a short time period. Preimmersion digital temperatures must be above 30°C. Hand and body warming may be required prior to immersion.

Using a thermistor probe to measure finger temperatures, the patient's hand is immersed in a container of ice water for 30 to 60 seconds. After the hand is dried, the fingertip pulp temperatures are measured every 5 minutes for 45 minutes, or until the temperature returns to preimmersion levels. Normal individuals will have a recovery time to preimmersion levels of less than 10 minutes. This test is very sensitive for detecting cold-induced vasospasm but is nonspecific, with approximately one half of patients with a positive test having no clinical symptoms of cold sensitivity.⁵⁰ Cold immersion testing is also uncomfortable and poorly tolerated by patients with significant Raynaud's syndrome symptoms. Pressures often fall to unrecordable levels in such patients.

A better test for cold sensitivity is the digital hypothermic challenge test as described by Nielsen and Lassen⁵¹ (Fig. 86.18). This test involves placing a finger cuff around the proximal phalanx on the test finger and perfusing the cuff with progressively cooler fluid. The pressure in the test finger is then compared with that in a reference finger that is not cooled. The Nielsen test is interpreted as positive for abnormal cold-induced vasospasm if the test finger pressure is reduced by more than 17% compared with the reference finger.

Other tests for cold-induced vasospasm include thermal entrainment, digital laser Doppler response to cold, thermography, venous occlusion plethysmography, and digital artery caliber measurement. None is widely accepted or employed.⁵²⁻⁵⁴

FIGURE 86.18. Device for performance of digital hypothermic challenge or Nielsen test. The cuff on the second finger is used to cool the test finger and measure digital pressure. This allows controlled application of cold to induce a vasospastic response. The fourth finger is the reference finger. Strain gauges on the finger tips are used to measure the digital pressures. See text.

UPPER EXTREMITY DUPLEX SCANNING

Duplex scanning of the upper extremity is carried out in a manner similar to arterial examination elsewhere. The origins of the brachial cephalic vessels can be difficult to visualize with duplex scanning. For examination of the origin of the subclavian artery, a 3- or 5-MHz transducer with a small footprint probe using the sternal notch as a window generally gives the best images. A recent study found that 48 of 50 right subclavian artery origins (96%) and 25 of 50 left subclavian artery origins (50%) could be visualized by color duplex scanning.⁵⁵

Criteria for stenosis at the origins of brachial cephalic arteries are slightly different than those used elsewhere. A peak systolic velocity ratio of 2 or more indicates stenosis at the origin of a brachial cephalic artery. Stenosis can also be implied by monophasic flow without actual visualization of a high-velocity jet and by reverse flow in a vertebral artery. Such additional criteria are necessary to assess the origins of the brachiocephalic vessels. If only peak systolic velocity ratios were utilized, there would be higher numbers of both false-positive and false-negative results.⁵⁵

More distally the upper extremity arteries are relatively superficial and fairly constant in location. They are best scanned with a higher-frequency probe such as a 7.5- or 10-MHz probe. Either a sector or linear scan head may be used, but in either case a standoff or mound of acoustical gel is helpful to visualize the vessel clearly and to assess the flow pattern within it. Color facilitates identification of the vessels (Fig. 86.19A, B), and tortuosity of the upper extremity arteries may be more easily seen with color flow imaging.

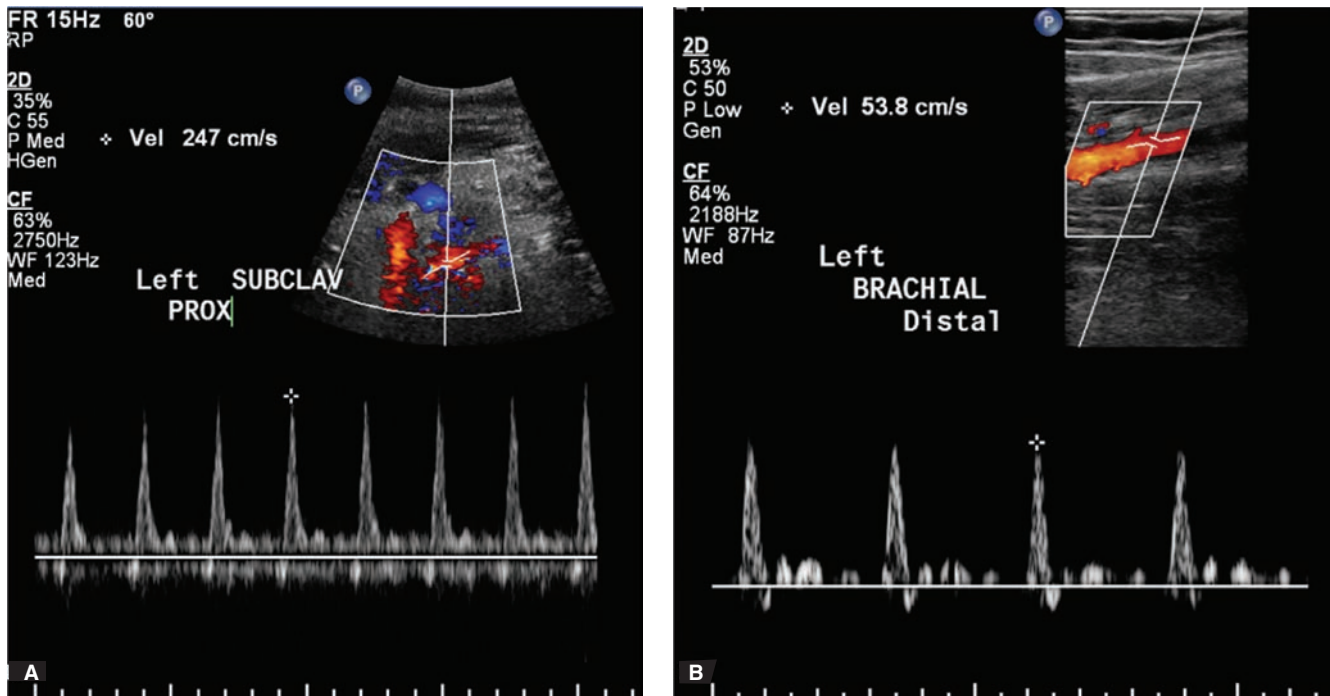

FIGURE 86.19. A peak systolic velocity of almost 250 cm/s (A) suggests a moderate to severe stenosis in the proximal subclavian artery. The hemodynamic significance of the lesion can be ascertained by comparing brachial blood pressures in the right and left upper extremities and inspecting distal waveforms. In this case, the ipsilateral brachial artery (B) has a normal velocity and a normal triphasic waveform, suggesting that the subclavian lesion is unlikely to be pressure reducing.

The interpretation of duplex findings in the upper extremity beyond the origins of the vessels is similar to the interpretation of B-mode images and Doppler signals gathered in other arterial systems.⁵⁶ Normal waveforms in the upper extremity arteries are usually triphasic. As elsewhere in the arterial system, stenoses will produce high-velocity jets, poststenotic turbulence, and dampened distal waveforms. There are, however, at present no specific frequency or velocity criteria with which to gauge the severity of stenoses in the upper extremity arteries. Some general guidelines are listed in Table 86.5. The diagnosis of arterial occlusion is made by imaging the artery and using the pulsed Doppler to show that there is no flow within the lumen.

For patients with unilateral symptoms who may have a surgically correctable lesion such as a subclavian artery aneurysm

or stenosis, duplex scanning is quite useful.⁵⁷ The duplex evaluation of aneurysms is based on the B-mode image appearance, with the most important feature being the size of the enlarged artery and the presence of intraluminal thrombosis that may serve as a source of distal embolization. Presence or absence of flow within the aneurysm can be determined by the Doppler component.

Duplex scanning may be of use in patients with suspected embolization to identify proximal aneurysms, but the evaluation should also include echocardiography to look for mural thrombi and valvular lesions. While duplex scanning alone cannot be used to make the diagnosis of Takayasu arteritis, it can be a helpful adjunct in following the progression or regression of arterial involvement in response to treatment.⁵⁸

TABLE 86.5

DUPLEX ULTRASOUND CRITERIA FOR EVALUATION OF UPPER EXTREMITY ARTERIAL STENOSIS

CONDITION	CHARACTERISTICS
Normal	Uniform waveforms; biphasic or triphasic waveforms; clear window beneath systolic peak
<50% diameter reduction	Focal velocity increase; spectral broadening; possibly triphasic or biphasic flow
>50% diameter reduction	Focal velocity increase; loss of triphasic or biphasic velocity waveform; poststenotic flow (color bruit)
Occlusion	No flow detected

VISCERAL ARTERIES

Mesenteric Arteries

- 8** Duplex ultrasonography can serve as a valuable noninvasive screening test for splanchnic artery stenosis in patients with possible chronic mesenteric ischemia and for follow-up of mesenteric artery reconstructions. Despite the accuracy of duplex detection of mesenteric artery stenoses, angiographic confirmation of high-grade stenoses or occlusion of the splanchnic vessels and appropriate history and physical examination are still required for the diagnosis of chronic mesenteric ischemia. The examination is technically difficult and is best performed by vascular technologists with extensive experience in intra-abdominal ultrasound techniques.

Interpretation of Mesenteric Duplex Ultrasound Studies. In healthy individuals, fasting blood flow velocity waveforms differ in the superior mesentery artery (SMA) versus the celiac artery (CA). Arterial waveforms reflect end-organ vascular resistance. The liver and spleen have relatively

FIGURE 86.20. A normal fasting superior mesenteric artery (SMA) waveform may exhibit reverse flow at the end of systole and relatively low end-diastolic velocity, reflecting relatively high resistance of the intestinal circulation in the fasting state.

high constant metabolic requirements and are therefore low-resistance organs. As a result, CA waveforms are generally biphasic, with a peak systolic component, no reversal of end-systolic flow, and a relatively high end-diastolic velocity. The normal fasting SMA velocity waveform is triphasic, reflecting the high vascular resistance of the intestinal tract at rest. There is a peak systolic component, often an end-systolic reverse flow component, and a minimal diastolic flow component⁵⁹ (Fig. 86.20).

Changes in Doppler-derived arterial waveforms in response to feeding are also different in the CA and SMA. Because the liver and spleen have basically fixed metabolic demands, there is no significant change in CA velocity waveform after eating. Blood flow in the SMA, however, increases markedly after a meal, reflecting a marked decrease in intestinal arterial resistance. The postprandial waveform changes in the SMA include a near doubling of systolic velocity, tripling of the end-diastolic velocity, and loss of end-systolic reversal of blood flow⁶⁰ (Fig. 86.21). These changes are maximal at 45 minutes after inges-

FIGURE 86.21. Postprandial superior mesenteric artery (SMA) waveform. There has been, in comparison to Figure 86.20, loss of end-systolic reverse flow and an increase in end-diastolic flow as resistance in the intestinal arterial circulation falls following feeding.

FIGURE 86.22. Color flow image and duplex-derived superior mesenteric artery (SMA) waveform in a patient with possible chronic mesenteric ischemia. A peak systolic velocity of 547 cm/s indicates a high-grade SMA stenosis and is compatible with a clinical picture of chronic mesenteric ischemia.

tion of a test meal and depend on the composition of the meal ingested. Mixed-composition meals produce the greatest flow increase in the SMA when compared with equal caloric meals composed solely of fat, glucose, or protein.⁶¹

Detection of Splanchnic Arterial Stenosis. Duplex ultrasound can detect hemodynamically significant stenoses in splanchnic vessels. In a blinded prospective study of 100 patients who underwent mesenteric artery duplex scanning and lateral aortography, a PSV in the SMA of 275 cm/s or more indicated an SMA stenosis of 70% or more with a sensitivity of 92%, a specificity of 96%, a positive predictive value of 80%, a negative predictive value of 99%, and an accuracy of 96% (Fig. 86.22). In the same study, a PSV of greater than or equal to 200 cm/s identified an angiographic celiac artery stenosis of 70% or more with a sensitivity of 87%, a specificity of 80%, a positive predictive value of 63%, a negative predictive value of 94%, and an accuracy of 82%.⁶²

Other duplex criteria for mesenteric artery stenoses are also in use. An SMA EDV greater than 45 cm/s correlates with an SMA stenosis of 50% or more with a specificity of 92% and a sensitivity of 100%, while a CA EDV of 55 cm/s or greater predicts a CA stenosis of 50% or more with a sensitivity of 93%, specificity of 100%, and accuracy of 95%.⁶³

Surgical revascularization of the mesenteric arteries is standard treatment for chronic mesenteric ischemia. Most often bypass grafts are constructed to the superior mesenteric and/or celiac arteries. Mesenteric artery bypass grafts can be followed postoperatively with mesenteric artery duplex scanning (Fig. 86.23). Flow velocities within mesenteric artery bypass grafts vary little with the origin of the graft (supraceliac or infrarenal aorta or a common iliac artery) and remain stable over time. Serially increasing velocities over time in a mesenteric bypass likely suggest the development of a graft or anastomotic stenosis.⁶⁴

Placement of an intraluminal stent is emerging as a viable alternative to surgical bypass in the treatment of mesenteric artery stenosis. Similar to the carotid artery (see earlier), there is reason to suspect duplex criteria developed for stenosis in native mesenteric arteries may not be applicable to stented superior mesenteric arteries. However, to date, only a single study has examined this issue. Mesenteric duplex scans pre- and postplacement of a superior mesenteric artery stent were compared and correlated with pressure gradients measured at

FIGURE 86.23. Color flow image of a common iliac-to-superior mesenteric artery (SMA) bypass graft.

the time of angiography. The data indicate that SMA stenting provides good anatomic results and significantly reduces angiographically measured pressure gradients. Duplex-measured SMA PSVs are reduced after stent placement but, despite good angiographic results, seem to remain in most cases above criteria predicting high-grade native artery SMA stenosis.⁶⁵

Renal Arteries

Indirect Assessment of Renal Artery Stenosis. Indirect methods to assess renal artery stenosis evaluate interlobar arteries. Decreased acceleration times and/or presence of tardus/parvus waveforms (waveforms with delayed or slowed upstrokes) may suggest the presence of a main renal artery stenosis. These techniques are quicker and easier to perform than direct examination of the main renal artery but have not been widely validated. Improved visualization of the main renal arteries with modern duplex scanners has made indirect methods of assessing the main renal artery essentially obsolete. These techniques are even less accurate in patients with bilateral stenoses and are not applicable in patients with a single patent renal artery.

Direct Assessment of Renal Artery Stenosis. Normal renal arteries have a PSV less than 180 cm/s and low-resistance waveforms reflecting the high metabolic demands of the kidney. A ratio of the PSV in the renal artery to that in the aorta (renal-to-aortic ratio [RAR]) of 3.5 or higher indicates a greater than or equal to 60% diameter-reducing renal artery stenosis (84% to 88% sensitivity, 97% to 99% specificity, 94% to 98% positive predictive value)⁶⁶ (Fig. 8.24). A PSV of greater than or equal to 200 cm/s has also been suggested to indicate a renal artery stenosis of 60% or more, while a velocity in the renal artery of greater than 185 cm/s has been suggested to indicate a less than 60% renal artery stenosis. Therefore, a renal artery can be considered normal when the PSV is less than 180 cm/s and the RAR is less than 3.5. With a PSV greater than 180 cm/s and a RAR less than 3.5, the renal artery can be considered to have a less than 60% stenosis. RARs of greater than 3.5 indicate a greater than 60% renal artery stenosis regardless of whether the renal artery PSV is less than

FIGURE 86.24. Renal artery waveform in a patient with severe hypertension. The high peak systolic velocity is compatible with a high-grade stenosis of the right renal artery.

or more than 180 cm/s.⁶⁷ When the end-diastolic velocity exceeds 150 cm/s, data suggest a greater than 80% renal artery stenosis.⁶⁸ The same criteria have been used to evaluate the patency of renal arterial reconstructions but, similar to stented carotid and mesenteric arteries, may need modification for stented renal arteries.⁶⁹

Predicting Success of Renal Artery Interventions.

EDVs tend to be lower in patients with renal insufficiency, indicating decreased diastolic flow and suggesting increased parenchymal resistance to blood flow. Decreased parenchymal diastolic velocities may therefore suggest renal parenchymal disease (Fig. 86.25). Many patients, 20% to 40%, treated with renal artery angioplasty and stenting or open surgical reconstructions do not have postprocedure blood pressure or renal function improvement. An estimate of resistance to flow within the renal parenchyma can be made by comparisons of EDVs and PSVs of renal artery waveforms obtained from renal

FIGURE 86.25. Low diastolic flow from the parenchyma of this transplanted kidney suggests parenchymal renal disease.

FIGURE 86.26. Venous flow is typically depicted below the baseline. Venous flow in the proximal lower extremity veins should be spontaneous, vary with respiration, and augment with distal compression.

parenchymal arteries. The so-called resistive index (RI) is calculated as follows:

$$RI = [1 - (EDV/PSV)] \times 100$$

In effect, a high resistive index, greater than 0.7, is bad, suggesting renal parenchymal disease, while a low resistive index is good, indicating healthy renal parenchymal tissues. Evaluation of parenchymal resistance has been suggested as a possible preprocedure predictor of clinical success of renal artery interventions.⁷⁰

VENOUS DISEASE

Acute Deep Venous Thrombosis

- 9 Physical examination is not sensitive or specific for the detection of acute deep venous thrombosis (DVT).⁷¹ Prior to the acceptance and widespread use of venous duplex scanning, impedance plethysmography (IPG) was employed as the initial noninvasive test for patients with suspected acute lower extremity DVT. IPG is a reasonably sensitive (87%) and specific (up to 100%) test for proximal lower extremity DVT in symptomatic patients.⁷²⁻⁷⁴ However, lower sensitivities for proximal DVT (65%) have been reported in studies that exclude clinical outcomes and only report in comparison to venography. IPG may not detect nonocclusive proximal DVT or occlusive proximal DVT present in parallel venous systems, such as duplicated femoral or popliteal veins, and cannot detect DVT isolated to the calf veins.^{75,76} While IPG is still sometimes used for clinical situations felt to require serial evaluations of the proximal veins, the limitations noted here make it a substandard examination for routine clinical assessment of lower extremity DVT.⁷⁷ Currently, color flow duplex scanning performed by skilled operators provides the most practical and cost-effective method for assessment of DVT of the lower and upper extremity veins as well as for superficial venous thrombosis.

At a minimum, vascular laboratory duplex ultrasound evaluation for lower extremity DVT should include examination of the common femoral, profunda femoral, femoral, and popliteal veins. Venous waveforms from the right and left common femoral veins should always be compared. A normal lower extremity examination will show patency of the veins on color flow imaging, collapsing of the veins with application of pressure by the ultrasound probe, and venous flow patterns in the common femoral and femoral veins that decrease with inspiration and increase with expiration. Flow within a patent

vein should also increase with application of compression distal to the site of examination (Fig. 86.26).

The primary ultrasound diagnostic criteria for acute venous thrombosis is failure of the vein to collapse with application of pressure with the ultrasound probe (Fig. 86.27). A continuous flow pattern in one common femoral vein and not the other suggests ipsilateral iliac vein thrombosis or external compression of the ipsilateral iliac vein. Bilateral pulsatile common femoral waveforms suggest volume overload, tricuspid regurgitation, or heart failure.

Not all venous ultrasound examinations for DVT are the same. Some vascular laboratories do not include evaluation of the calf veins as part of their routine evaluation for lower extremity DVT, even in symptomatic patients. This results from outdated perceptions of inaccuracy of calf vein ultrasound evaluation for DVT. Failure to perform a complete initial examination necessitates serial ultrasound examinations or alternative strategies to detect possible extension of venous thrombi initially isolated to the calf veins. Such strategies are inefficient, ineffective for noncompliant patients, and not cost-effective compared to a single stand-alone color flow duplex study of the proximal and calf veins in patients with suspected lower extremity DVT.

FIGURE 86.27. Failure of the common femoral vein to compress with pressure applied by the ultrasound scanhead indicates the presence of thrombus in the common femoral vein.

Limited ultrasound studies for acute DVT may include compression ultrasound (B-mode imaging only), duplex ultrasound (B-mode imaging and Doppler waveform analysis), and color Doppler alone. The sensitivities and specificities for detecting acute DVT differ among the examinations, and different examinations are appropriate for different veins. Compression ultrasound is typically performed for evaluation of proximal deep veins, specifically the common femoral, femoral, and popliteal veins. A combination of duplex ultrasound and color Doppler is more often used for calf and iliac veins. Color flow alone may be used to assess patency of the calf veins as they are difficult to reliably compress especially in subjects with larger legs.

Many factors will influence which venous segments can be evaluated in an individual examination. These include the presence of morbid obesity, lower extremity edema or tenderness, and the presence of immobilization devices and bandages. Overall, a complete color and Doppler examination has become the standard of care for assessment of lower extremity DVT. It is recommended that whenever possible, a venous duplex examination to exclude the presence of DVT consist of an evaluation of both the proximal and calf veins.

A well-trained technologist can interrogate calf veins in 80% to 98% of cases using a combination of B mode, Doppler waveform analysis, and color Doppler.^{78,79} Overall accuracy of venous ultrasonography in comparison to venography has been well established. The weighted mean sensitivity and specificity of venous ultrasonography (including all types) for the diagnosis of symptomatic proximal DVT are 97% and 94%, respectively.⁷⁷ As suggested earlier, in technically adequate studies, the sensitivity and specificity of color Doppler to identify isolated calf vein thrombosis exceeds 90%.⁷⁹ The high specificity of venous ultrasonography allows treatment for DVT to be initiated without further confirmatory tests, and the high sensitivity in diagnosing proximal DVT makes it possible to withhold treatment if the examination is negative.

Some ultrasound examinations are limited by practical constraints. Inability of the patient to fully cooperate with regard to positioning for the examination and/or intolerance of the pressure of the ultrasound scan head on the skin, or inability of the examiner to obtain a complete examination secondary to bandages, casts, or extremity wounds, may lead to a requirement for serial examinations. An alternative diagnostic procedure, such as catheter-based contrast, magnetic resonance (MR), or computed tomography (CT) venography, may be indicated when a complete ultrasound examination is not possible or if the patient cannot or is unlikely to return for a follow-up examination. Currently, repeat or serial venous ultrasonography is advisable for negative examinations in symptomatic patients highly suspicious for DVT in whom an alternative form of imaging is unavailable or contraindicated.

The diagnosis of pulmonary embolism (PE), like that for DVT, also cannot be established without objective testing. Several studies have evaluated lower extremity venous ultrasound examinations in patients suspected of PE. These studies, often employing ultrasound of only the proximal veins and nuclear medicine–based ventilation-perfusion (V/Q) scanning, unfortunately have little relevance to modern practice where complete proximal and distal vein ultrasound examinations are usually routine, and where CT pulmonary angiography (CTPA) or MR pulmonary angiography (MRPA) have largely supplanted V/Q scanning.

The rationale for venous ultrasonography in patients who present with symptoms of PE is that a diagnosis of DVT may indirectly suggest a diagnosis of PE, making additional investigation to exclude PE unnecessary in some clinical settings. However, ultrasound cannot make a definitive diagnosis of PE. Patients can have DVT and pulmonary symptoms or hemodynamic instability from causes other than PE.

Normal bilateral proximal venous ultrasound scans do not rule out PE. When PE is definitively present, DVT of the

proximal lower extremity veins is detectable by compression ultrasound in only 50% of patients.⁸⁰ When a PE is objectively diagnosed with no evidence of lower extremity DVT, the PE may have originated from pelvic veins or arm veins, or possibly embolized completely from a lower extremity vein. An objective diagnostic test for PE is therefore indicated in most cases. Currently, in most centers this would be a CT pulmonary angiogram.

Chronic Venous Insufficiency

The presence of venous insufficiency can also be evaluated with either air or photoplethysmography and with duplex scanning.⁸¹ In theory, air plethysmography (APG) can provide an analysis of overall venous hemodynamics including evaluation of the individual components of venous function, reflux, and the efficacy of the calf muscle pump. A flexible chamber is placed on the calf and volume changes are then induced by a series of positional and exercise maneuvers. Measurements derived from these maneuvers are then used to calculate measures of venous reflux (venous filling index [VFI]) and calf muscle pump function (ejection fraction [EF]) as well as a measure of overall venous function, termed the residual volume fraction. Of these values, VFI has the potential for being the most important. A VFI of greater than 2 mL/s indicates abnormal reflux, with values greater than 10 mL/s indicating increased risk of cutaneous changes associated with chronic venous insufficiency. APG, while theoretically interesting, is used only infrequently in clinical practice.

PPG is a variant of plethysmography techniques to assess venous reflux. It detects changes in the blood content of the skin that theoretically reflect venous volume. It consists of a light-emitting diode and a photosensor. The diode transmits light into subcutaneous tissues. Blood attenuates light in proportion to its content in tissue. The PPG machine amplifies the difference between the transmitted and reflected signal and converts it into a waveform. To assess for venous reflux the sensor is typically applied to the medial ankle area (Fig. 86.28). The patient performs a series of plantar and dorsal flexions of

FIGURE 86.28. Placement of photoplethysmographic (PPG) probes for assessment of venous reflux. See text.

FIGURE 86.29. Venous photoplethysmographic (PPG) waveforms in a patient with superficial venous reflux. The patient is asked to perform 10 dorsal and plantar flexions of the ankle, resulting in emptying the leg of venous blood. In the top panel the veins refill very rapidly, indicating the presence of venous reflux. Refill slows with application of a tourniquet to occlude the superficial veins, indicating this patient likely has only reflux in the superficial venous system and no deep venous reflux.

the foot, decreasing the venous volume of the extremity. The time for the waveform to return to baseline is termed the “venous recovery time” (VRT). A normal venous recovery is 20 seconds or greater. Shorter times indicate the presence of venous reflux. If the VRT returns to normal with the application of a superficial venous tourniquet, then the reflux is confined to the superficial venous system (Fig. 86.29). If the VRT does not correct with a superficial venous tourniquet, deep venous reflux is present. Neither APG nor PPG can provide information about the specific venous segments that are abnormal. That information can be provided by duplex ultrasound.

Duplex ultrasound can provide important physiologic and anatomic information in patients with possible chronic venous insufficiency. Both sites of reflux and of venous obstruction can be determined in deep, superficial, and perforating veins. In patients with valve incompetence, reflux can be stimulated and then detected with duplex using a Valsalva maneuver, manual compression proximal to the transducer, or release of compression distal to the transducer. The examination has been standardized with the patient upright and using deflation of a series of pneumatic cuffs at specific sites on the leg with the leg under examination not bearing weight. In the upright position, reflux stimulated by cuff deflation that lasts more than 0.5 second is indicative of pathologic reflux.⁸² The technique allows localization of reflux to specific venous segments and can serve as a valuable preoperative planning tool to

target specific venous segments for removal or reconstruction (Fig. 86.30A, B). It has a sensitivity of 82% and specificity of 100% for the identification of competent and incompetent perforating veins. Duplex determination of reflux sites and sites of venous occlusion as a means of assessing overall venous hemodynamics is not established. Currently, duplex assessment of venous reflux provides the basis of planning for the large majority of venous procedures designed to treat the manifestations of superficial venous reflux.

SELECTED MISCELLANEOUS EXAMINATIONS

Evaluation for Abdominal Aortic Aneurysm

- 10 Vascular laboratory ultrasound screening of males older than 65 years with a history of cigarette smoking for abdominal aortic aneurysm (AAA) has been shown to be effective in preventing aneurysm-related deaths in this cohort.⁸³ Ultrasound is highly accurate and reproducible in measuring the diameter of infrarenal AAAs (Fig. 86.31). Typically, patients with AAA diameters below accepted threshold levels for repair are followed with serial ultrasound examinations to monitor for enlargement of the aneurysm to a diameter where repair is indicated.

FIGURE 86.30. Technique (A) and popliteal venous waveform (B) with cuff deflation for duplex assessment and localization of venous reflux. Reflux lasting longer than 0.5 to 1 second is abnormal.

FIGURE 86.31. Ultrasound image of an infrarenal abdominal aortic aneurysm.

Evaluation of Aortic Endografts

Placement of endoluminal stent grafts is now standard therapy for most patients with AAA. With stent grafting of an AAA, the aneurysm is left in situ and blood flow diverted through the stent graft. Some stent grafts eventually leak at proximal or distal attachment sites. AAAs with these so called type I endoleaks are at risk for rupture. In addition, AAAs treated with stent grafts may also occasionally enlarge because of back-pressure in the aneurysm sac from patent lumbar vessels, type II endoleak. Patients whose AAAs enlarge in association with type II endoleaks after endografting are also considered at risk for aneurysm rupture.

Standard monitoring of endoluminal stent grafts is with serial CT scans to detect endoleak and changing sac diameter. However, there are increasing concerns about repeated doses of contrast and radiation exposure associated with serial CT scans. It now appears that many stent grafts can be followed with serial duplex ultrasound examinations. Duplex ultrasound is capable of measuring sac diameter and detecting both type I and II endoleaks. Even if an endoleak cannot be detected by ultrasound, an increase in sac diameter following stent grafting should prompt further investigation. In some centers duplex ultrasound has replaced CT scanning as the preferred method of follow-up of AAA stent grafts.^{84,85}

Evaluation and Treatment of Groin Pseudoaneurysms

Pseudoaneurysms can occur as a complication of an arterial puncture in the groin performed for diagnostic or therapeutic angiography. Groin pseudoaneurysms are readily detected with duplex ultrasound (Fig. 86.32). Color flow demonstrates a typical collection of flowing blood usually anterior to the artery from which the pseudoaneurysm originates. The native artery and pseudoaneurysm are connected by a so-called “neck.” To-and-fro flow within the neck of the pseudoaneurysm is characteristic and pathognomonic of a pseudoaneurysm arising from an arterial puncture.

Treatment of pseudoaneurysms may be with direct surgical repair or, utilizing the vascular laboratory, direct compression of the pseudoaneurysm until it thromboses using the ultrasound scanhead to both locate the pseudoaneurysm and apply pressure. Alternatively, the pseudoaneurysm is visualized with the ultrasound scanhead and a needle introduced into the

FIGURE 86.32. Color flow image of a groin pseudoaneurysm. See text.

body of the pseudoaneurysm for injection of small amounts of thrombin to induce thrombosis of the pseudoaneurysm.^{86,87} All of these techniques are effective, but currently direct thrombin injection is favored in most cases as it is relatively noninvasive, less painful, and more effective than prolonged compression alone.

Transcutaneous Oxygen Measurements

Measurements of transcutaneous oxygen (TCpO₂) can be performed as an aid in predicting healing of pedal lesions or healing of an amputation at the site where the measurement is taken (Fig. 86.33). In general, a TCpO₂ greater than 30 mm Hg indicates that healing is likely, measurements between 20 and 30 mm Hg are equivocal for healing, and measurements below 20 mm Hg indicate that healing is unlikely.⁸⁸ Measurements are not influenced by the presence of diabetes, but it has been suggested that the level for predicting healing be increased to 40 mm Hg in patients with diabetes. The test is less accurate in the presence of edema, cellulitis, or hyperkeratosis and in older patients.

FIGURE 86.33. Device for measuring transcutaneous oxygen pressures.

CHAPTER 87 ■ ENDOVASCULAR TREATMENT OF DISEASE

MATTHEW J. EAGLETON AND SUNITA D. SRIVASTAVA

KEY POINTS

- 1 The treatment of vascular disease has progressed significantly over the past several years with the evolution and application of endovascular procedures.
- 2 Endovascular treatment of carotid artery stenosis is less invasive and thus may be associated with a lower morbidity and mortality compared with carotid endarterectomy (CEA).
- 3 In order for carotid artery stenting to gain full acceptance, it must provide clinical outcomes that rival CEA.
- 4 With the advent of lower-profile sheaths, wires, and stents, percutaneous interventions have become more feasible and often the first-line treatment in the setting of mesenteric occlusive disease.
- 5 Percutaneous transluminal angioplasty is the treatment of choice for nonorificial atherosclerotic lesions and fibromuscular dysplasia.
- 6 Results from surgical revascularization and renal interventions are comparable.
- 7 The most important aspect of aortic endograft placement takes place prior to graft placement in determining whether a patient is indeed a suitable candidate for endograft placement, choosing an appropriate endograft device, and properly determining the size graft to be placed.
- 8 Postoperative surveillance is extremely important in patients undergoing endovascular abdominal aortic aneurysm repair.
- 9 Endovascular treatment of aortoiliac occlusive disease has become increasingly prominent over the past several years and has assumed a dominant role in the treatment of this disease.
- 10 There have been mixed results reported for outcomes of patients treated with percutaneous balloon angioplasty of femoropopliteal artery stenosis.

- 1 The treatment of vascular disease has progressed significantly over the past several years with the evolution and application of

endovascular procedures. In particular, the endovascular treatments of aortic aneurysm disease and carotid artery stenosis

have received intense scrutiny. Intravascular treatment of disease, however, is not a new concept. In the 1960s, radiologist Charles Dotter pioneered the concept of endovascular therapy.¹ He conceived the idea of using dilators of varying diameters to serially expand stenotic atherosclerotic lesions in the iliac arteries. Since then, the technology has continued to evolve. The development of guide wire-directed catheter technology has allowed physicians to percutaneously access nearly any blood vessel in the body. This combined with the development of the angioplasty balloon revolutionized percutaneous interventions and allowed for the treatment of stenotic lesions through a percutaneous arterial puncture. This procedure has been further enhanced by the development of metallic stents to assist in maintaining long-term patency of percutaneous angioplasty. With advancing technology, more endovascular procedures are being applied to the treatment of peripheral vascular disease. The goal of this chapter is to outline many of the applications of endovascular therapies for the treatment of peripheral vascular disease including technical aspects, complications, and outcomes.

BASIC CONCEPTS

The basic concept of most endovascular procedures is to obtain percutaneous access of a blood vessel and then to gain access across the lesion (either a stenosis or aneurysm) with a guide wire. This allows for endovascular treatment of the disease. Most arterial and venous access is obtained through a percutaneous puncture over the femoral vessels. From this location, most other branches of the arterial tree can be reached. Access from the femoral vessels, however, is not always possible or ideal, and in those instances percutaneous access is generally obtained through an alternate site, such as the brachial artery or the jugular vein. Once blood vessel access is obtained, a guide wire is inserted through the needle and into the artery or vein. Generally, the needle is then removed and a sheath is placed into the vessel over the wire. A sheath is a specialized piece of equipment, with a valve on one end, which allows continuous access to the blood vessel. This allows for continued introduction and removal of a variety of pieces of equipment

FIGURE 87.1. A: An example of two different endovascular wires. The one on the left has a straight tip, and it is coated with a hydrophilic substance, which increases its maneuverability in stenotic lesions. The wire on the right has a J-tip on the end, which allows it to be less traumatic to the arterial wall. B: An example of two different types of sheaths. The smaller sheath on the left is representative of the standard access sheath used for many endovascular procedures, whereas the larger one on the right demonstrates a more specialized sheath of a larger size with a pre-shaped curve. C: An example of angiographic catheters. The catheter on the left represents a straight catheter that is hydrophilic coated. It is an end-hole catheter that is used for selective catheterization of vessels. The catheter in the middle is a nonselective catheter that has a “pigtail” shape. It has multiple side holes and is most generally used for nonselective angiography. The catheter on the right is also a selective catheter that has a preformed shape that allows the interventionalist the ability to access vessels in unique anatomic locations.

while protecting the vessel wall from repeated trauma. Sheaths are available in a variety of sizes and a variety of shapes, and the exact sheath used depends on the procedure being performed and the blood vessel being accessed (Fig. 87.1).

The next tool to consider once a secured entry into the blood vessel is obtained is the guide wire, which allows remote access across the lesion. Guide wires are constructed in a variety of sizes; the three most commonly used sizes are 0.035, 0.018, and 0.014 inches in diameter. The length of the guide wire is also important and generally varies from 145 to 300 cm. The guide wire length needs to be long enough to cover the cumulative distance required both inside and outside the patient. This will vary based on lesion location, the type of procedure performed, and the type of other pieces of technology being used. There are several factors that are important in guide wire construction, including the stiffness of the wire, the coating on the wire, and the tip shape (Fig. 87.1). Some of these factors affect the steerability and trackability of the wire. Steerability refers to the ability to direct the intravascular tip of the wire by manipulating the extravascular portion, and trackability refers to the ability of the wire to allow a catheter to follow its course. The tip of the wire may be straight, angled, or J-tipped, and the tip may be stiff or floppy, making it less traumatic. Many wires have a tightly wound inner steel core that confers differing magnitudes of stiffness to the body of the guide wire. A surrounding wrap of lighter, more flexible wire helps prevent fracture and fragmentation while the guide wire is in use. Most guide wires have a hydrophilic coating of either polytetrafluoroethylene or silicone, which decreases the coefficient of friction during catheter exchange or while traversing a stenosis.

Catheters are another vital piece of equipment important in performing endovascular procedures. They are used to perform diagnostic procedures, maintain access across a lesion while a more suitable wire is exchanged, and support devices, such as balloons and stents, that are delivered to the lesion attached to the catheter. Catheters are constructed from a variety of materials including polyurethane, polyethylene, polypropylene, and nylon. Catheters are also available in a variety of diameters (measured in French) and lengths. Catheters constructed from polyethylene have a low coefficient of friction and are pliable with good shape memory. They are useful for selective catheterization. Polyurethane catheters are softer, are more pliable, and follow guide wires more easily but have a higher coefficient of friction. Nylon catheters are stiffer but tolerate higher flow rates. The construction of the

catheter affects several important properties, including trackability (the ability of the catheter to follow the direction of the wire), pushability (the ability of force applied on one end of the catheter to induce movement on the other end), crossability (the facility with which a catheter will follow the wire across a lesion), and steerability. The shape of the catheter's head is variable and dictates the catheter's function (Fig. 87.1). Functionally, catheters are classified as selective or nonselective. Nonselective catheters, also known as flush catheters, often have multiple side holes that allow large amounts of contrast to exit in a short period of time. These catheters' head shapes are usually either straight or curved. Selective catheters have only one end hole but are available in a variety of shapes, including straight, angled, reverse curved, and double-curved. The choice of catheter used depends on the type of procedure being performed.

An important tool in endovascular procedures is the angioplasty balloon. This is a balloon mounted on the end of a catheter that has the ability to be inflated and deflated through a port on the extravascular portion of the catheter (Fig. 87.2). The function of the angioplasty balloon is to provide a dilating force on the endoluminal surface of a blood vessel. As with all catheters, angioplasty balloon catheters are constructed with a number of variables, most specific to the balloon itself. Balloons vary in sizes that range from 1.5 to 40 mm, and they are selected with the intent to slightly overdilate the vessel being treated. The length of the balloon is also variable and can range from one to several centimeters in length. Typically, there are radiopaque markers on either end of the balloon that allow for accurate placement at the site of the lesion. The rounded area of the balloon that extends beyond the markers is termed the *shoulder* of the balloon. The length of the shoulders of the balloon varies from balloon type to balloon type. In addition, balloons are constructed of a variety of types of material, which alters the way in which the balloons respond to inflation. Most balloons are constructed of polyethylene, polyethylene terephthalate, or other low-compliance polymers. These allow for a low or noncompliant balloon, which allows the balloon at high inflation pressures to exert more radial force without increasing the balloon diameter. Other balloons, particularly those used in aortic endografting, are more compliant and will continue to change diameter with increases in pressure, thus reducing the radial force applied. Furthermore, specialized balloons have been developed that provide specific functions while performing an angioplasty. One such balloon is a "cutting balloon." This is a balloon that

FIGURE 87.2. A–C: These pictures depict a self-expanding stent at various stages of deployment. **A:** The stent ensheathed on the catheter prior to deployment. **B:** The stent partially deployed. Note the expansion of the stent in the unsheathed portion. **C:** The self-expanding stent fully deployed. **D–F:** These pictures depict a balloon-expandable stent at various stages of deployment. **D:** The balloon-expandable stent mounted on a catheter prior to deployment and **(E)** at the start of expansion. **F:** A fully expanded balloon-expandable stent adjacent to the inflated balloon used to deploy it.

has strips of metal, or blades, along the length of the balloon that can cut the area of stenosis, assisting in the balloon's ability to dilate the region.

As discussed in more detail later, balloon angioplasty is often supplemented with the placement of an intravascular stent. The evolution of stents has occurred along two fundamental design philosophies: balloon-expandable stents and self-expanding stents (Fig. 87.2). Stents are composed of a variety of metals including steel, nitinol, tantalum, platinum, and various metal alloys. The construction is also variable and includes laser cut, woven, knitted, coiled, or welded. The construction of the stent helps to determine its properties. The ideal stent properties are high radial force, minimal induction of neointimal hyperplasia, longitudinal flexibility, high radiopacity, radial elasticity, ability to conform to the vessel, low profile with high expansion ratio, no foreshortening, durable, and affordable.² Balloon-expandable stents are best exemplified by the prototypical Palmaz stent. The basic mechanism is a metal tube (stent) placed around a balloon. The balloon is expanded, thus dilating the metal tube, which then maintains the nominal diameter of the balloon. Most are made of stainless steel alloy, providing greater radial and hoop strength with minimal foreshortening, which allows for exact placement. These same properties, however, allow little flexibility and render the stents susceptible to irreversible deformation when subjected to external compressive forces. The prototype of the self-expanding stents is the Wallstent. These stents function on the principle of elasticity, as the stents self-expand to their nominal diameter when released from a constrained state within the delivery catheter. A stent of a larger nominal diameter than the target vessel is chosen so that it exerts a continuous outward expansile force. The final diameter is the equilibrium that is reached between the elastic recoil of the vessel and the expansile force of the stent. Some general properties of self-expanding stents are that they are flexible, track better than balloon-expandable stents, and have crush resistance. Unfortunately, these stents foreshorten during placement and thus can only be accurately positioned at one end. With improving technology and the development of better alloys (e.g., nitinol, a nickel and titanium alloy), many of the adverse properties of both balloon- and self-expanding stents are overcome and they approach closer the properties of the ideal stent. As discussed in more detail later, the specific choice of stent to use in a given situation depends on the procedure being performed.

CAROTID ARTERY INTERVENTIONS

Stroke occurs in nearly 700,000 patients annually in the United States resulting in an estimated 164,000 deaths and contributing \$54 billion in health care costs.³ Nearly one third of strokes are attributable to carotid artery stenosis, and nearly 200,000 carotid endarterectomies (CEAs) are performed each year in the United States to help prevent this debilitating problem.⁴ The value of CEA to reduce the risk of stroke has been proven in a number of randomized, prospective clinical trials. CEA has been documented to reduce the incidence of both stroke and combined stroke and death in symptomatic patients with a stenosis greater than 70%.⁵ In the North American Symptomatic Carotid Endarterectomy Trial, life-table estimates of the cumulative risk of any ipsilateral stroke at 2 years were 26% in patients treated with aspirin alone versus 9% in those patients treated with CEA. For major or fatal ipsilateral stroke the estimates were 13.1% and 2.5% for medical versus surgical treatment, respectively. For patients with asymptomatic disease, although the results are not as dramatic, there is a significant decrease in stroke risk with CEA versus medical therapy. The Asymptomatic Carotid

Atherosclerosis Study randomized 4,657 patients with greater than 60% stenosis to receive either CEA or medical therapy.⁴ The aggregate risk over 5 years for ipsilateral stroke and any perioperative stroke or death was 5.1% for surgical patients and 11.0% for patients treated medically. The results from the Asymptomatic Carotid Surgery Trial were very similar.⁶ CEA has also proven durable, with reoperation for recurrent stenosis reported from as low as 1% to as high as 9%.

2 Endovascular treatment of carotid artery stenosis is less invasive and thus may be associated with a lower morbidity and mortality compared with CEA. The underlying indications for treatment of carotid artery stenosis do not change with the application of percutaneous techniques. However, carotid artery stenting must at least demonstrate clinical equipoise with CEA to become an accepted alternative. In the United States, most applications of carotid artery stenting currently are reserved for patients who are characterized as "high risk" for conventional CEA or in patients who are enrolled in ongoing clinical trials. In May 2007, the Centers for Medicare and Medicaid Services (CMS) expanded coverage of carotid angioplasty and stenting to those patients at high risk for carotid endarterectomy with symptomatic high-grade stenosis of 50% to 70% and asymptomatic stenosis of greater than 80%.

Percutaneous treatment of carotid artery stenosis was first described in 1980 by Kerber et al.,⁷ at which time they described the application of percutaneous transluminal balloon angioplasty (PTA) of an atherosclerotic lesion. Since that time the procedure has evolved tremendously and now includes the application of either a balloon-expandable or self-expanding stent. Currently, patients are premedicated with aspirin and either ticlopidine or clopidogrel at least 1 day prior to the procedure. Heparin anticoagulation is standard once arterial access has been obtained. The majority of the procedure does not differ significantly from the performance of PTA and stent placement at other sites. Percutaneous arterial access is obtained through a common femoral artery puncture. Brachial artery access is possible, although more difficult, if femoral access is prohibitive. Selective catheterization of the common carotid artery is performed utilizing one of a variety of preformed catheters that best fit the anatomic variability. The common carotid artery is cannulated with a 6- or 7-French introducer sheath or guide catheter. An inability to access the common carotid artery with these devices due to vessel tortuosity or anatomic variation is the principle cause of procedure failure. During advancement of the sheath, distal guide wire access is maintained in the external carotid artery. Guide wire access across the lesion in the internal carotid artery is then obtained. A wire with a filter or net for cerebral protection is advanced to allow for embolic protection prior to carotid intervention. In cases where there is thrombus, ulcerated plaque, or higher risk of embolization with initial wire placement, reversal of flow devices can be utilized. This technique involves placement of a special balloon catheter allowing occlusion of both the common carotid artery and the external carotid artery. A separate 9-French sheath is placed in the femoral vein and reversal of flow through the internal carotid is initiated to facilitate protected carotid stenting.

Typically, the lesion requires predilation with a smaller angioplasty balloon to facilitate placement of the stent. Little outcome variability has been described when comparing the placement of a balloon-expandable versus a self-expanding stent, although most often self-expanding stents are placed due to the balloon-expandable stents' vulnerability to compression.⁸ If necessary, the stent is extended from the internal carotid artery into the common carotid artery, effectively "jailing" the external carotid artery ostia.

One of the most catastrophic complications of carotid artery stenting is stroke, which is most often due to atheroemboli or thromboemboli dislodged at the time of the procedure. Unfortunately, unlike in peripheral interventions when a surgical therapy can often be used to correct an interventional

FIGURE 87.3. Angiograms from a patient undergoing a carotid artery stent. **A:** There is an 85% recurrent stenosis within the internal carotid artery (arrow). The patient had undergone a carotid endarterectomy 1 year prior. **B:** After wire access was obtained across the lesion, a balloon occlusion protection device was placed prior to angioplasty and stenting. This current angiogram shows placement of a self-expanding stent at the site of the internal carotid narrowing (top arrow). The balloon occlusion device can be seen in the distal internal carotid artery (bottom arrow). Note the absence of contrast beyond the protection device. After stent deployment and prior to balloon deflation, the contents of the common carotid artery and proximal internal carotid artery will be aspirated and discarded. **C:** After stent deployment, there is resolution of the internal carotid artery narrowing.

complication, it is rare that an operation can correct distal cerebral embolization. To decrease the incidence of these complications, several cerebral protection devices have been developed and are utilized at the time of stent placement. Several series evaluating the efficacy of cerebral protection devices have shown up to an 80% reduction in the rate of acute neurologic events related to embolic complications compared with unprotected procedures.^{9–12} There are a number of different types of cerebral protection devices, including distal occlusive balloons, distal filter systems, and proximal protection systems. The distal protection devices must cross the lesion prior to stent placement and before they are opened; thus, some embolization may occur as they cross the lesion. Distal occlusive balloons consist of a 0.014-inch guide wire with the balloon on the distal portion. The balloon is inflated in the extracranial internal carotid artery distal to the lesion occluding blood flow (Fig. 87.3). After placement of the stent, stagnant blood and debris is suctioned from the region before blood flow is resumed by deflating the balloon. Distal filter systems are placed in a similar location, but allow for continuous blood flow through the filter while it traps emboli. Proximal protection systems provide protection by occluding flow in the common carotid artery and external carotid artery. The collateral flow through the circle of Willis then provides a “back-pressure” that prevents distal embolization during the procedure. After stent placement, the blood in the internal carotid artery is then evacuated to prevent embolization of debris when antegrade flow is reestablished.

Carotid artery stent placement complications can be divided into three stages.¹³ Stage I complications occur primarily during access of the common carotid artery. Stage II complications occur during positioning of the distal protection device in a straight cervical segment of the internal carotid artery. Stage III complications occur during predilation, stent deployment, and postdilation of the stent. When a neurologic event does occur, one should have an understanding of the cerebral circulation to proceed with neurologic rescue procedures.¹⁴ In patients with a transient ischemic attack (TIA) or minor stroke and a normal angiogram, medical management should ensue. In patients with minor or major strokes and evidence of occlusion of an intracranial vessel, catheter-directed

thrombolysis should be initiated and glycoprotein platelet receptor antagonists administered.¹³

3 In order for carotid artery stenting to gain full acceptance, it must provide clinical outcomes that rival CEA. Early studies evaluating carotid stent outcomes were derived from single-institution case series and registries. The first large series reported was by Yadav et al.¹⁵ and included 126 carotid stenting procedures performed in 107 patients that were at high risk for CEA due to medical comorbidities. The 30-day incidence of ipsilateral major stroke and death was only 1.6%. At 6 months, however, there was a 4.9% incidence of asymptomatic restenosis. Lal et al.¹⁶ reported their results from 122 carotid stent procedures performed in 118 patients. Similarly, there was a low 30-day stroke and death rate of 3.3%. This analysis applied Kaplan-Meier curves and predicted cumulative in-stent restenosis, defined as a recurrent stenosis of greater than 80%, in 6.4% of the patients at 5 years. None was associated with onset of symptoms.

The largest collection of patients undergoing carotid artery stenting comes from a review of the Global Carotid Artery Stent Registry.¹⁷ This report, from 53 participating centers in Europe, South and North America, and Asia, is based on a survey questioning the performance and complications of carotid artery stenting. The registry began in 1997 and since then has accrued 12,392 procedures in 11,243 patients. The technical success rate was 98.9%, with technical success defined as less than 30% residual stenosis. Thirty-day complication rates were 3.07% for TIA, 2.14% for minor strokes, 1.2% for major strokes, and 0.64% for deaths. Thirty-day combined stroke and procedure-related death rate was 3.98%. In support of the use of cerebral protection devices, 4,221 patients underwent carotid artery stenting with cerebral protection, which resulted in a stroke and procedure-related death rate of 2.23%, compared with 6,753 patients who underwent a procedure without cerebral protection and had a rate of 5.29%. This difference was consistent even when patients were stratified into those who were treated for symptomatic disease and those who were asymptomatic. Restenosis rates of 5.6% were reported at 48 months, although because of the registry format Kaplan-Meier curves were not possible. A 48-month neurologic event rate was reported at 4.5%.

There are several other registries, including ARCHER (Acculink for Revascularization of the Carotids in High Risk Patients), CABERNET (Carotid Artery Revascularization using the Boston Scientific EPI Filter Wire EX/EZ and the EndoTex Nex Stent), BEACH (Boston Scientific EPI-A Carotid Stenting Trial for High Risk Surgical Patients), SHELTER (Stenting of High Risk Patients Extracranial Lesions with Emboli Removal), and MAVERIC (Evaluation of the Medtronic AVE Self-Expanding Carotid Stent with Distal Protection in the Treatment of Carotid Stenosis), that are based on high-risk entry criteria. More recent trials under way include EMPiRE (Embolic Protection with Flow Reversal) Clinical Trial, evaluating the reversal of flow device, and the ViVA (ViVEXX Carotid Revascularization) trial, employing the Bard ViVEXX carotid stent platform with the Emboshield filter device.

To better evaluate the outcomes of carotid artery stenting, in particular compared with CEA, several randomized trials have been organized and are currently under way. The first large trial of carotid angioplasty was the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS).¹⁸ This study enrolled a total of 504 patients with 251 in the endovascular arm and 253 in the carotid endarterectomy arm. Within the endovascular cohort, only 55 patients underwent stent placement with the remaining (158) being treated with balloon angioplasty alone. Distal embolic protection was not available at the time of the trial and thus not utilized for the percutaneous procedures. There were no major differences in 30-day outcomes and no difference in ipsilateral stroke in 3 years between the groups. The trial has been criticized for the lack of embolic protection, high incidence of restenosis in the balloon angioplasty arm, and higher stroke rate overall for both CEA and carotid interventions.

The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) was the first prospective randomized trial reported for carotid artery stenting.¹⁹ The goal of this trial was to compare the safety and effectiveness of carotid artery stenting with embolic protection to CEA in high-risk patients. Patients were eligible if they had a greater than 50% stenosis and were symptomatic or had a greater than 80% stenosis and were asymptomatic. High risk was defined as patients with at least one of the following criteria: contralateral carotid artery occlusion, radiation therapy to the neck, previous CEA with recurrent stenosis, contralateral laryngeal nerve injury, difficult surgical access, heart failure, open heart surgery within the previous 6 weeks, myocardial infarction within the preceding 4 weeks, unstable angina, severe pulmonary disease, tandem lesions, or age older than 80 years. The primary outcome evaluated were rates of death, stroke, or myocardial infarction at 30 days. At 30 days, the CEA group ($n = 151$) had a composite endpoint rate of 12.6%, whereas the carotid stent group ($n = 156$) (performed with cerebral protection) had a rate of 5.8% ($p = 0.047$). At 1 year, carotid artery stenting was not statistically superior to CEA but it also wasn't inferior in the 1-year endpoints of stroke, myocardial infarction, and death. The 1-year major adverse event rate was 12.1% for carotid artery stenting and 20% for CEA. However, when the incidence of non-Q-wave myocardial infarction was removed, the difference in adverse events was not statistically different. The inclusion of myocardial infarction as a composite endpoint was controversial for several reasons. The two groups differed in types of anesthesia (general for CEA and local for carotid artery stenting) administered, as well as antiplatelet regimen (Plavix in the carotid artery stenting group and none in the CEA group). These differences may have accounted for the reduced incidence of myocardial infarction in the carotid artery stenting group. Another major criticism of the trial has been the larger number of patients assigned to the registry group (406) rather than stenting (344) due to the rationale that patients who were unfit for surgery should be directly assigned to the stent registry. The trial was halted due to the lack of enrollment and,

notably, less than 50% of patients actually underwent randomization.

As was stated earlier, in order for carotid artery stenting to gain full acceptance, it must provide clinical outcomes that rival CEA. Randomized trials comparing the outcomes in patients considered to be of conventional risk, either symptomatic or asymptomatic, are under way. The Carotid Revascularization Endarterectomy versus Stent Trial (CREST) is a prospective randomized trial of symptomatic patients with carotid stenosis of greater than 50% by angiography or greater than 80% by duplex ultrasound (US). It was expanded to also include an asymptomatic arm for stenoses greater than 60% by angiography and 70% by duplex US. The enrollment goal is listed as 1,500 patients. In 2004, the CREST investigators published the interim results from the lead-in phase of CREST.²⁰ It showed that the periprocedural risk of stroke and death after carotid artery stenting increased with age. In this group of 749 patients, a 12.1% incidence of stroke and death was reported in patients aged 80 and older.

Recently, two European trials have been published evaluating CEA and carotid artery stenting. The Stent-Protected Percutaneous Angioplasty of the Carotid versus Endarterectomy (SPACE) trial was a European study comparing carotid artery stenting with CEA in symptomatic patients.²¹ Thirty-five multinational sites participated with randomization of 1,200 patients and 1,183 patients analyzed. With stroke and death as endpoints, this study failed to demonstrate the noninferiority of carotid artery stenting. The study was terminated due to lack of funding and poor results of carotid artery stenting. Interestingly, despite a large stent group of 567 patients, only 27% were treated with embolic protection devices and the majority of patients underwent stenting without protection. Critics of the study blame the poor outcome of carotid artery stenting on the inconsistent and infrequent use of embolic protection. Similarly, the Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S) study reported data comparing carotid artery stenting with CEA in high-grade symptomatic patients.²² Thirty-five sites in France enrolled 259 patients for CEA and 261 patients for carotid artery stenting. The decision to employ cerebral protection and dual-antiplatelet therapy in the carotid artery stenting group was left to the discretion of the individual investigators. The 30-day incidence of stroke or death was 9.6% in the carotid artery stenting group and 3.9% in the CEA group, and the study failed to prove noninferiority of carotid artery stenting. It was halted prematurely due to the significantly higher stroke and death rates in the carotid artery stenting group. The study was widely criticized for the level of investigator experience and variability of carotid artery stenting technique. Proponents of carotid artery stenting felt that the operators were not appropriately skilled in the devices and procedures, which resulted in poorer outcomes for carotid artery stenting than in other studies where investigators were more experienced.

While CREST was to complete enrollment by 2008, other prospective randomized trials, such as the Transatlantic Asymptomatic Carotid Intervention Trial (TACIT), the Asymptomatic Carotid Trial (ACT-1), and the Asymptomatic Carotid Surgery Trial (ACT-2), are under way to evaluate optimal therapy with respect to asymptomatic stenosis.

MESENTERIC ARTERY INTERVENTIONS

Chronic and acute mesenteric ischemia are well-described conditions resulting from occlusive disease of the splanchnic vessels. The prevalence of mesenteric occlusive disease among the elderly has been reported at 17.5%.²³ Symptomatic disease is usually a result of occlusion or stenosis of two of the three mesenteric vessels. A delay in diagnosis and treatment of this

FIGURE 87.4. A: Lateral aortogram demonstrating occlusion of the superior mesenteric artery (SMA, arrow) in a patient with postprandial abdominal pain and weight loss. B: The occlusion was crossed with a guide wire (arrow) and subsequently balloon angioplasty and stented. C: Completion angiography reveals resolution of the occlusion with antegrade flow in the SMA. The patient's symptoms resolved.

clinical syndrome can result in bowel infarction and death. Surgical therapy with revascularization and bowel resection has been the traditional mode of treatment.

Percutaneous therapy for mesenteric occlusive disease was first described in 1980 by Furer et al. and Uflacker et al. in two separate reports.^{24,25} Furer et al. reported the first balloon angioplasty of a superior mesenteric lesion with success. The early experience with percutaneous treatment favored balloon angioplasty, and several small series reported excellent initial results.^{26–28} They were limited, however, by early restenosis ranging from 17% to 25% with a mean follow-up of 25 to 39 months. Failures were attributed to extrinsic compression, elastic recoil, and refractory disease. This led to the application of primary stenting, particularly in the setting of ostial disease.

Early series evaluating the efficacy of mesenteric stenting were limited by the small numbers of patients and short follow-up.^{29–31} Later series have emerged with larger numbers of patients and interventions. The Cleveland Clinic experience reported by Kasirajan et al.³² compared outcomes in 28 patients treated with endovascular therapy with those in 85 patients treated with open surgical therapy. Both groups were matched in comorbid risk factors, number of occlusive vessels involved, and duration of symptoms. They differed, however, in the age of onset and presentation. The median age for the endovascular group was 72, whereas in the open surgery group it was 65. Although both groups had similar postprocedure complication rates and 3-year restenosis rates, the percutaneous group had a higher incidence of recurrent symptoms. This may have been related to the number of lesions treated in the percutaneous group, which was one, compared to the surgical group, who had more than one vessel revascularized. Rose et al.³³ found similar results in 1995 in their retrospective review of surgical and percutaneous revascularization modes in patients. The mortality and complication rates were similar and the open surgical group underwent multivessel revascularization in the Kasirajan review.³² Long-term pain relief was 67% at 9 months in the endovascular group and 82.7% at 34.5 months in the surgical group. The authors suggested that the differences in symptomatic relief stemmed from the number of vessels revascularized. A series by Sharafuddin et al. retrospectively evaluated 25 patients in whom 28 procedures were performed with 96% technical success and found no difference in clinical outcome or patency rates in patients who were treated for simple stenotic lesions, occlusions, or complex lesions.^{33a} The patency rates and complication rates were similar to other recent studies.^{34,35}

Recently, Sarac et al. investigated the results of percutaneous mesenteric revascularization and evaluated predictors of outcomes including morbidity and death.³⁶ Sixty-five patients

underwent 87 mesenteric interventions with cumulative 1-year patency rates that included primary patency of 65%, primary assisted patency of 97%, and secondary patency of 99%. Symptomatic relief was immediate in 85% of patients and 75% experienced relief beyond 1 year. Diminished patency rates were associated with hypertension, chronic obstructive pulmonary disease (COPD), and bowel dysfunction. Patency, complications, and survival were no different despite number of vessels treated or types of stents used. Decreased survival was noted in patients with COPD, and no patient who underwent bowel resection after intervention survived. This series supports the endovascular treatment of occluded mesenteric vessels with similar patency and survival as stenotic visceral vessels.

With the advent of lower-profile sheaths, wires, and stents, percutaneous interventions have become more feasible and often the first-line treatment in the setting of mesenteric occlusive disease (Fig. 87.4). As with renal disease, the lesions are often ostial and respond best to stent placement. In the setting of multioclusive lesions, solitary treatment of the superior mesenteric lesion will often suffice. The role of stent grafts and biodegradable stents in the visceral vessels have yet to be evaluated.

RENAL ARTERY INTERVENTIONS

Renovascular hypertension is the most common cause of secondary hypertension, and obstructive renal lesions account for 5% of such cases.^{37,38} Without treatment, such lesions can result in progressive renal dysfunction with ischemic nephropathy, congestive heart failure, and renal atrophy.³⁹ Renal revascularization options include both surgical and percutaneous interventions. Although both therapies offer similar technical results, the morbidity and mortality of surgical revascularization ranges from 17% to 31% and 2% to 7%, respectively.^{40–43} Transcatheter therapy offers similar patency, with fewer complications and shorter hospital stay.

Percutaneous transluminal angioplasty is the treatment of choice for nonorificial atherosclerotic lesions and fibromuscular dysplasia. The first percutaneous transluminal angioplasty of the renal artery was reported by Gruntzig et al. in 1978.⁴⁴ Technical success for percutaneous transluminal angioplasty in this setting has been reported at 90% in several series.^{45–47} The incidence of restenosis in the setting of angioplasty, however, is high. Reports from Martin et al. and Weibull et al. in separate series have reported a 30% incidence of restenosis.^{40,45} Elastic recoil and extensive atherosclerotic aortic and orificial plaque limit the application of balloon angioplasty in patients with ostial disease and account for the high recurrence rate afterwards.

FIGURE 87.5. Angiograms from a patient undergoing angioplasty and stenting of a right renal artery stenosis. **A:** Flush aortogram that reveals a high-grade right renal artery stenosis (arrow). **B:** Wire access is obtained across the lesion, and a sheath is advanced up to the origin of the renal artery. A balloon-expandable stent (arrow, prior to deployment) is placed at the level of the stenosis (arrow). **C:** After deployment of the stent, there is no residual stenosis.

Selective placement of stents in the renal arteries (Fig. 87.5) evolved following the first report by Palmaz et al.⁴⁸ in animal models. Although first used in the setting of elastic recoil or dissection after balloon angioplasty, the use of stenting has become a primary modality for renal artery stenosis, particularly in the setting of ostial disease.^{49,50} Several studies have evaluated the efficacy of stenting for ostial disease. The Erasme study prospectively assessed the safety and results of Palmaz stenting of the renal artery in 10 centers with 106 patients. The investigators demonstrated technical success in 95% of arteries and a 16.9% restenosis rate at 8 months, of which 10 out of 15 lesions were successfully redilated.⁵¹ Rees et al.⁵² reported similar success in the United States with a multicenter trial evaluating the Palmaz stent in ostial renal stenosis. Single-center reports have also verified the high technical success rate of primary stenting with restenosis rates of 15% to 20%.^{53,54}

Despite the high procedural success rate and lower restenosis rate than balloon angioplasty, the effects of renal artery stenting on hypertension and renal function have varying results. Improvements in hypertension control after renal artery stenting have been demonstrated in several series and vary from 49% to 80%, whereas azotemic benefit is more variable, with most centers reporting stabilization of renal function rather than improvement.^{50,53,55–57} A multicenter registry report by Dorros et al.⁵⁶ evaluated the 4-year follow-up in 1,058 patients and found significant improvement in blood pressure control, a decrease in the number of antihypertensive medications from 2.4 to 1.9, and stabilization of serum creatinine levels.

- 6 Results from surgical revascularization and renal interventions are comparable. Higher complication rates are reported with concurrent repair of aneurysmal disease or other visceral stenosis.^{53,58} Cambria et al.⁵⁹ reviewed 285 renal revascularizations and reported an operative mortality of 5.6% and an 8.1% mortality in procedures that involved an aortic anastomosis. Hallett et al.⁴² documented an operative mortality of 7.1% in a series of 652 renal operations. In contrast, complications related to renal interventions are most commonly groin hematoma and puncture site trauma, although atheroembolic phenomena and contrast nephropathy also occur.^{51,60} Lower-profile systems, embolic protection devices, meticulous technique, increased experience, and nonnephrotoxic radiographic agents have been used to reduce the incidence of emboli and renal failure.^{61–63}

Recently, Kashyap et al.⁶⁴ evaluated PTA and stenting in patients with renal artery stenosis and declining renal function. This study evaluated 125 patients, and 67% experienced improvement or stabilization of their glomerular filtration rate (GFR). The fate of the incidental renal artery stenosis with percutaneous treatment was evaluated in a retrospective series by Suliman et al.⁶⁵ This study evaluated 128 patients, of which 78

underwent intervention for high-grade renal artery stenosis. The authors concluded that isolated renal artery stenting resulted in the lowering of systolic and diastolic pressures in patients who had an increase in the number of antihypertensive medications. Other parameters, however, such as GFR and serum creatinine, were not affected. The management of isolated renal artery stenosis with percutaneous intervention is not clear and is not supported. Renal artery interventions have been shown to have excellent technical results and patency comparable to open surgical revascularization. The modest recurrent stenosis rate can be treated adequately with repeat intervention and balloon angioplasty. However, its long-term effect on preservation of renal function remains to be proven. Long-term outcomes with both surgery and percutaneous therapy are better in patients with normal renal function, and success with either intervention is limited in the setting of parenchymal loss and elevated serum creatinines.^{66–68}

AORTIC INTERVENTIONS

Endografting for Aortic Aneurysms

Abdominal aortic aneurysm (AAA) repair has had favorable results, but a less invasive procedure with fewer physiologic stresses has evolved over time. Parodi et al.⁶⁹ reported the first clinical use of endovascular AAA repair. Since that time, the application of aortic endografting for the treatment of AAA has significantly progressed and continues to do so. The current indications for endovascular repair of AAA remain the same as for conventional operative repair. It provides many potential benefits over conventional repair, however. It requires small groin incisions instead of a large abdominal one, which may decrease the incidence of postoperative pulmonary complications. There is decreased retroperitoneal dissection and thus a lower risk of perioperative bleeding. There is no or minimal aortic occlusion, which reduces the intraoperative hemodynamic stresses compared with open aneurysm repair.⁷⁰ These benefits may broaden the scope of aneurysm repair to patients who previously were deemed untreatable due to comorbidities.

Endograft Construction. The design of an aortic endograft can greatly affect the ability to place the device in a patient. One design component that is important for effective endograft placement is the delivery system. This is the equipment that houses the endograft in a compact fashion allowing it to be delivered to the proper anatomic location. Most endografts are placed through the common femoral artery and iliac artery system. The size of the delivery system must be smaller than the lumen through which it must pass. Inadequate vessel diameter or the presence of extensive calcifications can inhibit

endograft placement. The majority of available endografts easily traverse an iliofemoral segment of 7 to 8 mm in diameter. Another feature of the endograft delivery system is its flexibility, which allows it to traverse a tortuous iliac artery. Some tortuosity can be corrected or “straightened” with the use of a stiff guide wire; however, this is not always possible or desirable. Delivery systems composed of long, flexible, tapered tips pass more easily than those with short, stiff, blunt tips.⁷¹

Two general classifications of endograft construction exist: unibody and modular. A unibody device is a single-piece graft. This single piece includes the main body and both limbs. This composition decreases the risk of endoleaks as there are fewer sites of component apposition. However, a larger delivery system is often required, and there is less flexibility in obtaining the correct length of the graft. The modular system includes endografts that are composed of two to three pieces. Generally there is a main body that may have one attached limb and one or two docking limbs. These types of devices can be introduced through smaller delivery systems and offer a greater degree of flexibility with regard to placement. With multiple sites of graft-graft apposition, however, there is increased risk of endoleak.

Graft composition further varies by the material that is used to construct the graft and the metal “skeleton” that is used to support it. Graft material ranges from thin-walled polytetrafluoroethylene to polyester. The graft material is supported by a metal framework (stent) that is composed of stainless steel, Elgiloy, or nitinol. The graft support can be placed inside the graft material, an endoskeleton, or outside the graft material, an exoskeleton. Grafts can be fully supported, having stent material throughout, or only partially supported, with portions of the graft having only material and no metallic support. The graft skeleton provides several key elements to endograft construction. The metal skeleton provides some degree of radial force that helps to provide a seal to prevent blood flow around the graft and a point of fixation. Some devices have hooks or barbs in the proximal aspect of the skeleton that help to anchor the graft onto the aortic wall and prevent migration. Other grafts have a bare stent that extends above the level of the fabric that helps to anchor the graft in the pararenal and suprarenal portion of the aorta, at a point where less disease may be present. The other function of the metal skeleton is to provide columnar strength to the graft, which helps to prevent migration. The skeleton may play an important role in prevention of graft kinking as it crosses tortuous anatomy, but the lack of a skeleton may be important in allowing a graft to adapt more readily to morphologic changes that occur after aneurysmal exclusion, without dislodgment of attachment sites.

Anatomic Requirements for Graft Placement. There are several anatomic requirements for the successful placement of an aortic endograft. Exact requirements vary with specific device design, but the key aspects remain the same. These include an appropriate aortic neck, a distal sealing zone, and a suitable path for the endograft to be placed through. The aortic neck is defined as the area of the aorta cephalad to the aneurysm, below the level of the renal arteries, in which the aortic endograft will be placed. This area is important for two reasons: (a) it is the site of proximal fixation that will prevent the device from migrating distally and (b) a circumferential seal must be obtained in this region to prevent blood leakage around the graft and into the aneurysm sac. In general, a 15-mm length of aortic neck is required below the level of the most caudal renal artery and above the level of the aneurysm to meet these needs. Several devices employ the use of a suprarenal, uncovered stent to provide additional protection against graft migration. Other aortic neck characteristics are important in determining whether a patient is an ideal endograft candidate. These include neck angulation, the shape of the neck, and the quality of the neck. Acute angulation of the

neck can greatly affect the ability to obtain a proximal seal. Aortic neck angulation greater than 60 degrees compared with the centerline is often considered prohibitive for endovascular aneurysm repair. The shape of the aortic neck will also affect the ability to obtain a seal and fixation. A conical-shaped neck, defined as an increase in diameter over the course of 15 mm by more than 10%, is felt to be a contraindication to routine aortic endografting. In addition, the presence of circumferential thrombus or severe aortic wall calcification can negatively affect the ability to obtain a seal and fixation.

The iliofemoral arterial system is important for endograft placement because it provides the route for graft placement, as well as the site for obtaining a distal seal. Many of the features important in an aortic neck for obtaining a seal and fixation are also important in the iliac arteries. The presence of thrombus, calcification, and tortuosity can significantly hinder the iliac limb seal. Most available endograft systems require at least a 15-mm segment of iliac artery to be of adequate caliber and free of significant disease to obtain a distal seal.

7 Endograft Placement. The most important aspect of aortic endograft placement takes place prior to graft placement in determining whether a patient is indeed a suitable candidate for endograft placement, choosing an appropriate endograft device, and properly determining the size graft to be placed. These determinations are best made based on thin-cut helical computed tomography scans and in some cases with the addition of diagnostic angiography. The majority of endografts are placed through the femoral arteries that have been operatively exposed. The aorta is cannulated with a guide wire and catheter. Small boluses of contrast agent are delivered to identify the renal arteries to avoid covering them. Due to the often angulated nature of an aneurysmal aorta, it can be necessary to focus the image intensifier at an oblique cranial-caudal view to obtain the best view of the renal arteries. The device is generally placed over a stiff guide wire and positioned to allow the most extensive coverage within the aortic neck without intruding on the ostia of the renal arteries. Every device has its own unique deployment instructions and discussion of them is beyond the scope of this chapter. Depending on the construction of the endograft, following deployment of the main body (which may include an attached ipsilateral limb), the ipsilateral limb and contralateral limbs are placed.

8 Postoperative surveillance is extremely important in patients undergoing endovascular AAA repair. Complications may be asymptomatic at first and not present clinically for several years.⁷²⁻⁷⁴ Protocols for graft surveillance vary from institution to institution, but most entail four-view abdominal plain film radiographic evaluation and intravenous contrast, thin-cut computed tomography (CT) scanning. Major imaging generally occurs at 1, 6, and 12 months and then yearly thereafter. From these images, assessment can be made to evaluate for migration, changes in aneurysm size, and the presence of endoleaks. An alternative method used to track aneurysms following endograft repair is via calculation of aneurysm volume. Aneurysm volume is determined from three-dimensional reconstructions of spiral CT scans. Aneurysm morphology can change after endograft exclusion, and thus a measurement of the volume may be a more accurate assessment of changes in aneurysm size.^{75,76} Duplex US would provide a less invasive and less costly means of following aortic aneurysms following endovascular exclusion, but it does not yet provide the sensitivity and specificity obtained by CT scans.⁷⁷ The addition of US contrast agents may improve its efficacy; however, its use currently is not routine.⁷⁸

Complications Associated with Aortic Endograft Placement. A number of problems can arise during the placement of an aortic endograft, and there are several that can arise in the follow-up period. The following paragraphs outline some of the more common problems encountered.

Iliac Artery Disease. As the primary route of insertion for most endografts is via the iliofemoral arterial system, the presence of atherosclerotic disease, aneurysmal disease, and tortuosity in the iliac arteries can greatly affect the ease with which these grafts are placed. In cases of iliac artery lumen narrowing secondary to atherosclerotic disease and severe vessel tortuosity, advancement of the device despite the presence of resistance can result in vessel rupture. Iliac rupture occurs in 1% to 2% of cases of endograft placement.^{79,80} Occasionally, iliac artery narrowing can be dealt with by predilation of an occlusive lesion with balloon angioplasty. Preprocedural iliac stent placement, however, can be prohibitive to endograft placement and is discouraged. An alternative is to use an iliac conduit. An iliac conduit involves suturing a prosthetic graft to the iliac artery (and occasionally the aorta), even if it is aneurysmal. The device is placed through the conduit and into the aorta. The ipsilateral limb is then “landed” in the conduit and the end of the conduit is anastomosed to the common femoral artery. The distal end of the common iliac artery can be oversewn at a level to allow continued perfusion of the hypogastric artery in a retrograde fashion. Alternatively, the hypogastric artery can be anastomosed to the iliac conduit.

Iliac artery ectasia and aneurysmal disease can cause a problem obtaining a distal seal. Enlarged common iliac arteries are present in up to 30% of patients presenting for endovascular aneurysm repair.^{81–83} Some endografts allow for the placement of larger iliac limbs, or flared limbs, that can obtain seals in ectatic iliac arteries. In those that do not, however, the distal seal may need to be obtained in the external iliac artery. This generally requires sacrifice of the hypogastric artery by coil embolization prior to the procedure. The presence of a hypogastric artery aneurysm requires the same approach. Rarely is bilateral hypogastric artery exclusion required, but, when it is, it is performed in a staged fashion. Hypogastric embolization is associated with side effects in up to 50% of patients. Buttock claudication is the predominant complaint, occurring in 12% to 50% of patients, but it generally resolves within several months.^{81–83} Patients requiring embolization of the more distal branches of the hypogastric artery are at an increased risk for developing symptoms, although bilateral hypogastric embolization has not been reported.^{83,84} Coil embolization of the hypogastric artery is not necessary in the presence of a common iliac artery aneurysm provided that there is a 5-mm neck of iliac artery proximal to the hypogastric origin as well as a 15-mm neck in the external iliac artery.⁸⁵ This anatomic arrangement allows for an adequate seal and can be successful in up to two thirds of patients requiring coverage of the hypogastric artery.

TABLE 87.1**ENDOLEAK CLASSIFICATION COMPLICATIONS**

■ TYPE OF ENDOLEAK	■ DEFINITION
I	Arise secondary to inadequate sealing at either proximal aortic or distal aortic/iliac attachment sites
II	Arise secondary to patent branch vessels off of the aortic sac (i.e., inferior mesenteric artery or lumbar artery)
III	Arise secondary to defects in the fabric of the graft or at the junction zone between modular components
IV	Arise secondary to diffuse “leaking” of blood between the interstices of the fabric, or from suture holes at the sites where the graft is attached to the stent
V	Applied to the scenario in which the aneurysm sac remains pressurized in the absence of a discernible endoleak—termed <i>endotension</i>

Endoleaks. An endoleak is the persistence of blood flow outside of the endograft within the aneurysm sac. Endoleaks are classified according to their etiology, and currently five different types have been described (Table 87.1).^{86–88} Type I endoleaks arise from inadequate sealing at either proximal aortic (allowing antegrade flow) or distal iliac (allowing retrograde flow) attachment sites. Type II endoleaks arise from patent branch vessels off of the aortic sac that allow for retrograde flow into the aneurysm. Such branches include patent lumbar arteries and a patent inferior mesenteric artery (Fig. 87.6). Type III endoleaks develop from defects in the fabric of the graft or at the junction zone between modular components. Type IV endoleaks develop secondary to diffuse “leaking” of blood between the interstices of the fabric or where the graft is sutured to a stent. Type V endoleaks are applied to the scenario in which the aneurysm sac remains pressurized resulting in subsequent aneurysmal enlargement, despite no demonstrable evidence of blood flow into the aneurysm sac. The pressure applied to the aneurysm sac causing it to continue to expand, in this situation, has been termed *endotension*.⁸⁹

FIGURE 87.6. Radiologic images from a patient who underwent an endograft repair of an abdominal aortic aneurysm (AAA). The patient had a known type II endoleak, but subsequently developed an increase in the size of the aneurysm. **A:** Computed tomography scan revealing a type II endoleak. **B:** Angiogram revealing the branch off the hypogastric artery that was contributing to the endoleak (arrow). **C:** Subsequent coil embolization of this vessel (arrow) led to resolution of the endoleak.

Controversy with regard to this concept exists. Some argue that this merely represents a type I, II, III, or IV endoleak in which the defect is large enough to allow blood flow into the aneurysm sac, but it either occurs intermittently or is too small to be visualized by conventional means.⁷¹

Types I and III endoleaks are associated with an increased risk of aneurysm expansion and possible rupture, and thus should be treated.^{90,91} Treatment of these lesions can be accomplished with the placement of an extension cuff over the site of the leak. Alternatively, for type I endoleaks, placement of a large balloon-expandable stent at the level of the leak may increase the radial force at that level and seal the leak. Failure to resolve a type I or III endoleak in an endovascular fashion should result in the conversion to an open procedure with standard repair of the aneurysm and removal of the endovascular device. Type II endoleaks are rarely associated with aneurysm rupture.⁹² At least 10% to 15% of patients will be identified with a type II endoleak during follow-up.^{93–96} Type II endoleaks are generally observed unless they are associated with an increase in aneurysm size or are associated with aortic pulsatility on physical examination. Arteriography is the next step in the evaluation of a patient with a type II endoleak associated with these findings. Supers elective arterial canalization can be performed with embolization of feeding vessels. An alternative approach is via direct aneurysm sac puncture, during which sac pressures can be measured as well as the injection of contrast to identify the feeding vessels precisely.⁹⁷ Sac pressure measurements may be an indicator of the presence of an endoleak, even if it is not detected by routine imaging. The use of implantable intrasac pressure transducers to monitor patients following endovascular repair is currently under investigation.⁹⁸

Limb Thrombosis. Thrombosis of an iliac limb of an aortic endograft occurs in up to 11% of patients.^{99–102} There are a number of factors that have been suggested to place patients at increased risk for developing graft limb thrombosis. The lack of stent support within an iliac limb has been shown to increase the risk of thrombosis by nearly eightfold compared with intrinsically supported limbs.¹⁰¹ Intuitively, the presence of atherosclerotic disease and luminal narrowing within the iliac artery increases the risk of limb thrombosis.¹⁰⁰ Oversizing of the iliac limb causes the graft material to have a significant amount of infolding, thus narrowing the intraluminal diameter and placing the limb at increased risk for thrombosis.¹⁰² Extension of the limb into the external iliac artery can contribute to the risk of limb thrombosis due to the change in vessel diameter, as well as due to kinking caused by the acute angulation the artery takes as it exits the pelvis.¹⁰⁰ Most patients present with limb thrombosis within the first 6 months following endograft repair. Management of patients with acute limb thrombosis is dictated by the presenting symptoms. As many as one third of patients remain asymptomatic and require no intervention.¹⁰⁰ Most patients, however, are symptomatic and are managed with a femoral-femoral artery bypass. Few patients are successfully treated with thrombolysis or graft thrombectomy followed by endovascular repair of the underlying problem.

Migration. Stent graft migration complicates abdominal aortic endografting in 9% to 45% of cases.^{96,103–105} Migration is a known risk factor for the delayed development of a type I endoleak and subsequent delayed aneurysm rupture or late conversion.¹⁰⁵ Blood flow is the main displacing force that causes graft migration. This force is counteracted by the frictional forces of the graft against the aortic wall, particularly at the aneurysm neck. These frictional forces can be affected by the length of the neck or the presence of thrombus and calcifications. Albertini et al.¹⁰⁴ evaluated patients that developed migration or a delayed type I endoleak. Neck angulation and neck diameter were the two factors associated with their development. Morphologic changes in the aortic aneurysm and aneurysm neck have been suggested to contribute to graft migration. Aneurysm neck dilation occurs mostly in the first

2 years after graft placement and has been shown to be independently associated with device migration.^{105,106} This finding, however, has not been supported by all series.¹⁰⁷

Outcomes. Endograft repair of AAA has a low mortality rate (less than 3%) and subsequent rates of aneurysm rupture are reduced to 1% per year.^{91,96,108,109} The need for a secondary intervention, however, is not insignificant.¹¹⁰ In the EUROSTAR registry, reporting on 1,023 patients with follow-up of 12 months or longer, 186 (18%) of patients required a secondary intervention. The majority of these (76%) were accomplished through a transfemoral approach, and the rest required an intra-abdominal or extra-anatomic procedure. The rates of freedom from intervention at 1, 3, and 4 years were 89%, 67%, and 62%, respectively. Mortality was higher in those patients requiring a secondary procedure and was more frequently associated with those requiring an intra-abdominal intervention. Similar results have been reported from single-institution series. Montefiore Medical Center reported secondary procedure rates of 10%, whereas the Cleveland Clinic Foundation had a secondary intervention rate of 15%.^{108,111} Univariate analysis revealed that secondary procedures were more common in patients with large major and minor sac axes, in patients who received a large aortic stent because of a proximal endoleak present at the initial repair, and in patients who received treatment later in the course of the review. This latter finding is thought to be secondary to the increased complexity of cases.

There have been several studies comparing the results of aortic endograft repair of AAA with conventional surgery. Early studies that compared outcomes of endografting with historic controls or concomitant surgical arms suggested that endovascular repair is associated with a shorter initial hospital stay compared with open surgery. This difference, however, is negated if the total number of hospital days, including subsequent ones for secondary procedures, is taken into consideration.¹¹² Schermerhorn et al.¹¹³ evaluated quality-adjusted life expectancy after endovascular AAA repair compared with open surgical repair using a Markov decision-analysis model. Endovascular data were derived from the EUROSTAR registry, whereas the open aneurysm repair data came from the 1995 Medicare claims for elective repair of nonruptured AAA. A case-based analysis of 70-year-old men revealed the life expectancy after endovascular AAA repair was 7.09 quality-adjusted life years compared with open AAA repair of 7.03 quality-adjusted life years. This represents a difference of approximately 3 weeks. Sensitivity analysis, however, revealed that for individuals younger than 64 years, open surgical repair results in a significantly greater quality-adjusted life expectancy.

There have been two direct comparisons of abdominal aortic endografting to conventional surgery.^{114,115} The Dutch Randomised Endovascular Aneurysm Management (DREAM) trial group reported on the outcomes of a randomized prospective trial comparing open repair with endovascular repair in 345 patients with AAA.¹¹⁴ This study demonstrated clinical equipoise between conventional surgery and endovascular aneurysm repair. Operative mortality was 4.6% in the open surgical arm and 1.2% in the endovascular arm ($p = 0.10$). The rate of moderate and severe systemic complications, however, was significantly lower in the endovascular arm (11.7%) compared to the open surgical arm (26.4%, $p < 0.001$). Endovascular Aneurysm Repair (EVAR) trial 1 evaluated a randomized controlled trial of 1,082 patients deemed anatomically suitable for endovascular repair and fit for open surgery.¹¹⁵ While all-cause mortality did not differ between the two arms, there were significantly lower aneurysm-related death rates in the EVAR group (4%) compared to the surgical arm (7%, $p = 0.04$) at 4 years. This is directly related to lower operative mortality rates. There were, however, higher rates of long-term complications requiring reintervention in the EVAR group. This improvement in aneurysm-related mortality, however, does not necessarily lead to improved outcomes in those patients deemed too high risk for conventional surgery.¹¹⁶

Thoracic Aortic Endografting. Aortic endografting is no longer limited to the abdominal aorta. To date, in the United States, three thoracic aortic endografts have been approved for commercial use, and several more are undergoing clinical investigation. The construction and delivery of these devices is very similar to that of abdominal aortic endografts, and the general principles of endografting as outlined previously apply. Some differences, however, do exist. These devices are often larger in diameter than their abdominal counterparts, and thus require a larger sheath for delivery. This increased delivery system diameter can lead to more difficulty in traversing the iliac arteries and a higher rate of conversion to an iliac conduit. In addition to the size and tortuosity of the iliac arteries, the thoracic aorta can often provide an additional site of tortuosity and angulation, making it more difficult to maneuver the device into position. There can often be a significant size differential between the proximal and distal landing zones, thus requiring multiple tubular pieces in order to cross a lesion. Despite these increased difficulties, thoracic aortic endografting has been very successful. Five-year results of the Gore TAG device have been published.¹¹⁷ In this trial, 140 thoracic aortic endografts were compared to standard open surgical controls ($n = 94$). At 5 years, aneurysm-related mortality was lower for the endograft arm (2.8%) compared to the surgical arm (11.7%, $p = 0.008$). In addition, major adverse events were lower in the endograft arm (57.9% vs. 78.7%, $p = 0.001$). As more data on the outcomes of thoracic aortic endografting are collected, we will be better able to assess its usefulness and long-term clinical limitations.

Thoracoabdominal Aortic Aneurysms. The current commercially available endograft systems are limited in their application to patients with suitable anatomy. This predominantly means that they are limited to patients who have sufficient normal aorta on either side of the aneurysm that will allow for the apposition of the endograft to the aortic wall, without covering any significant side branches. The future of aortic endografting, however, revolves around the development of grafts that will allow exclusion of an aneurysm but preservation of blood flow to critical branch vessels, thus allowing treatment of such complex anatomy as thoracoabdominal aortic aneurysms. Advanced endovascular technologies that allow treatment of more complex aneurysms that involve or abut the visceral segment use devices termed *fenestrated* or *branched* aortic endografts. These endovascular devices overcome problems with inadequate sealing zones by extending the sealing and fixation regions of the stent graft proximally or distally without sacrificing branch vessels. These devices require a detailed understanding of imaging studies, adjunctive endovascular devices, interventional techniques, and high-level operative/interventional facilities.

Fenestrated endografts are grafts that have a hole, or fenestration, that accommodate a single or multiple side branches. These devices are ideal for increasing the landing zone of an aortic endograft that has some neck, just not enough. The typical type of aneurysm treated with these devices would be a juxtarenal aneurysm. The wall of the endograft is in apposition to the aortic wall at the level of the vessel ostia. As this distance increases, such as when the critical vessel arises from the aneurysm itself, a branched endograft is necessary. A branched endograft allows for a cuff of fabric to bridge the gap between the endograft and the branch vessel (Fig. 87.7). The cuff or branch creates an overlap zone between the stent graft and the branch artery. The branch is often mated with the target vessel using an additional covered stent (Fig. 87.7). These types of systems have only been employed, in the United States, in clinical trials. The largest series was presented by the Cleveland Clinic.¹¹⁸ This series describes the use of branched endografts in 73 patients treated for thoracoabdominal aortic aneurysms. Technical success was achieved in 93% of the patients, and there were no conversions to open repair. Five technical failures occurred: one was secondary to a death

FIGURE 87.7. Three-dimensional reconstructions of an aorta from a patient with a thoracoabdominal aortic aneurysm (A) prior to repair and (B) after endovascular repair with a branched aortic endograft. The arrows demonstrate the branches arising from the endograft that supply the superior mesenteric artery and the celiac artery. SMA, superior mesenteric artery.

within 24 hours, and the others were related to the inability to gain access to one of the target vessels. Major complications occurred in 14% of patients and included paraplegia (2.7%), new-onset dialysis (1.4%), myocardial infarction (5.5%), and stroke (1.4%). Although this aspect of aortic endografting is still in its infancy, it is clear that the refinement of this technique will break down almost all current anatomic barriers of aortic endografting and allow for the treatment of the aorta from its origin through its bifurcation.

Aortoiliac Angioplasty and Stenting

9 Endovascular treatment of aortoiliac occlusive disease has become increasingly prominent over the past several years and has assumed a dominant role in the treatment of this disease. Factors including decreased morbidity compared with conventional surgery, shorter hospital stays, and equivalent patency rates have contributed to this change.

The specific indications for treatment of aortoiliac occlusive disease are independent of the approach to treatment, either endovascular or conventional surgery. An intervention is generally indicated if disabling claudication or limb-threatening ischemia is present. Clinically, pain starts in the thighs and buttocks and is often present in combination with lower extremity discomfort. Erectile dysfunction may be present in men. Weakened femoral pulses and decreased segmental blood pressures are indications of proximal disease. Indications for PTA, as opposed to PTA with primary stenting, are changing. Historically, PTA was the first approach and the application of a stent was reserved for suboptimal results of primary PTA, defined as a persistent reduction of the lumen diameter of 30% or more. A resting mean blood pressure gradient of 5 mm Hg or greater or a systolic blood pressure gradient exceeding 10 mm Hg is also considered significant. Provocative testing performed by the intra-arterial injection of a vasodilatory agent (25 mg papaverine or 100 to 200 μ g nitroglycerine) may unmask a lesion and reveal a significant blood pressure gradient. Other indications for stent placement include eccentric stenosing plaque, arterial dissection, and when recanalization of an occluded segment is performed. With the ease with which stent placement can be performed, a more liberal approach to stenting is occurring.

Balloon dilation of iliac arteries is a relatively simple procedure. A retrograde transfemoral approach is the most widely

FIGURE 87.8. Angiograms from a patient who presented with disabling claudication of his left lower extremity. **A:** Aortogram revealed an area of stenosis in the proximal common iliac artery on the left (arrow). A pressure gradient was measured across this lesion and was found to be 30 mm Hg. **B:** The patient underwent placement of a balloon-expandable left iliac artery stent. To preserve the lumen of the right common iliac artery, a “kissing” balloon technique was performed in which a balloon was expanded in the right common iliac artery as the balloon-expandable stent was placed in the left common iliac artery (arrow). **C:** Angiographic resolution of the stenosis. There was also resolution of the pressure gradient.

used approach, although crossover procedures from the contralateral side can be performed. Following the use of angiography to identify the site of the lesion, a guide wire is advanced across the lesion. Once this is performed, the dilation balloon, sized to match or slightly exceed the normal vessel diameter, is inflated. The inflation device allows for the measurement of pressure within the PTA balloon, and often dilations to a pressure of 6 to 8 atmospheres of pressure are performed. Balloon dilation causes a fracture in the arterial plaque creating a local dissection, stretching the media and adventitia. Completion arteriography with or without pressure measurements is generally performed. The exact mechanism of stent deployment varies depending on the type of stent placed (balloon expandable or self-expanding) and the manufacturer. Stents are advanced across a lesion in a “protected” fashion. This entails the advancement of a sheath across the lesion, the advancement of the stent within the sheath to the level of the lesion, and then the retraction of the sheath. This protects the stent from being dislodged as it crosses a tight stenosis. If primary stent placement is considered, predeployment balloon angioplasty may be necessary to allow for advancement of the sheath and the stent.

Percutaneous treatment of chronic iliac artery occlusions is technically feasible. This is approached in a similar fashion as in a stenotic, nonocclusive lesion. Access to the artery is obtained in either a retrograde or antegrade fashion. The rate-limiting step in this scenario is obtaining wire access across the lesion. This is often accomplished with a combination of a catheter and a hydrophilic wire. Long areas of occlusion, as well as densely calcified lesions, can hinder the technical feasibility. Once wire access across the lesion is obtained, the stenosis can undergo balloon angioplasty to obtain a flow channel. This is best supported with the use of a stent after predilation.

Aortic bifurcation lesions present a unique situation as balloon angioplasty or stent placement in the origin of a common iliac artery may cause occlusion of the contralateral artery orifice. To overcome this problem, a technique termed *kissing balloon* or *kissing stent* placement is used (Fig. 87.8). This is the simultaneous placement of PTA balloons or stents that traverse the ostia of both common iliac arteries. If stents are used, it is mandatory that the proximal ends of both stents are parallel so that the flow into one stent is not hindered by the other. In most cases, the use of noncompressible, balloon-expandable stents are most beneficial in this procedure. Below the level of the aortic bifurcation, however, self-expanding stents are perfectly acceptable.

Iliac artery stent placement is technically successful in up to 97% of patients.¹¹⁹ Technical complications occur in less than 6% of interventions and include subintimal dilation, dissec-

tion, arterial rupture, inability to cross the lesion with a wire, and distal embolization. Belli et al.¹²⁰ reported in their series that only 2.8% of patients developed complications requiring surgery, and only 0.9% required reconstructive bypass. Clinically significant distal embolization occurs in up to 1% of patients undergoing iliac artery PTA and stent placement. Silent peripheral embolization has been detected by Doppler ultrasound in 90% of patients immediately following iliac artery PTA, but this decreases with time.¹²¹ Symptomatic embolization can be treated by a variety of endovascular methods, including suction thrombectomy and thrombolytic therapy. If these methods are unsuccessful, surgical thromboembolism is necessary.

Iliac artery dissection during PTA is reported in less than 1% of patients.¹²² Half of the patients develop significant lumen compromise. Dissections are treated with prolonged balloon inflation to “tack down” the flap, or with placement of an intra-arterial stent. If endovascular therapy is unsuccessful, operative treatment includes iliac endarterectomy, iliofemoral artery bypass, femoral-femoral artery bypass, and aortobifemoral artery bypass grafting. Arterial dissection has been reported in 10% of patients undergoing iliac artery stent placement.¹²³ Nearly two thirds of the dissections caused a flow-limiting lesion that required the placement of an additional stent. Vessel injury is related to balloon oversizing and the degree of arterial calcification. Iliac artery rupture during balloon dilation and stent placement has been reported in up to 0.9% of cases.^{124,125} Vessel disruption can present with uncontained hemorrhage, contained hemorrhage, or pseudoaneurysm formation. The key to initial management is to maintain guide wire access across the site of disruption. Control of the hemorrhage can be obtained with the insertion of an angioplasty balloon to tamponade the site of injury. If prolonged balloon tamponade does not achieve hemostasis, the placement of a covered stent is warranted. Uncontrolled hemorrhage demands operative intervention, but balloon occlusion proximal to the site of injury can afford time to prepare for surgery. Risk factors for rupture are similar to those for dissection and include the presence of a high-grade stenosis with heavy calcifications. Other risk factors include the use of oversized balloons and manual inflation without manometric control.

Results of iliac artery balloon angioplasty have been well documented. Johnston et al.¹²⁶ prospectively analyzed the results of 984 patients who underwent PTA, 684 of whom had aortoiliac angioplasty. Outcomes were assessed by Kaplan-Meier analysis. Twelve percent of the patients were treated for iliac artery occlusions, and the rest had nonocclusive stenoses. Initial success, defined as a combination of clinical factors and

ankle-brachial index, was achieved in 88.6% of patients. This dropped to 48.2% at 60 months. Predictors of success included the indication for operation (with better results in patients treated for claudication vs. limb-threatening ischemia), site of angioplasty (common iliac artery lesions favoring external iliac artery lesions), and lesion severity (stenoses favoring occlusions). Becker et al.¹²⁷ reported a meta-analysis involving 2,679 procedures. Five-year patency rates for this group were 72%. More recently, Tegtmeier et al.¹¹⁹ reported a single-institution experience in 200 patients with a technical success rate of PTA alone of 88% and a 5-year patency of 85%.

Outcomes from treatment of iliac artery stenosis with PTA and stent placement have also been evaluated with long-term clinical data. The outcome from the use of the self-expanding Wallstent in 140 patients was evaluated by Martin et al.¹²⁸ Primary patency was 81% at 1 year and 71% at 2 years, and secondary patency was 91% and 86%, respectively. Similar results were obtained by Vorwerk et al.¹²⁹ They followed 118 patients with primary patency rates of 95% at 1 year, 88% at 2 years, and 82% at 4 years, and secondary patency rates were 96%, 93%, and 91%, respectively. Palmaz et al.¹²⁴ evaluated the outcomes of the use of the balloon-expandable Palmaz stent in 486 patients enrolled in a multicenter trial. Technical success occurred in 99% of patients with clinical follow-up patency of 90% at 1 year and 84% after 2 years. A meta-analysis evaluating outcomes of iliac artery PTA and stent placement in 1,300 patients, with a variety of types of stents, was performed by Bosch and Hunink.¹³⁰ Four-year primary patency rates were 77% for stenotic lesions treated with iliac stenting and 61% for occlusive lesions in patients with claudication, and 67% and 53%, respectively, in patients with limb-threatening ischemia. The risk of long-term failure was reduced by 39% after stent placement compared with PTA alone. Iliac artery stent patency rates are significantly lower in women and in patients with renal insufficiency and critical limb ischemia.¹³¹ Kashyap et al. compared aortoiliac angioplasty and stenting to surgical reconstruction, in a retrospective fashion.¹³² In this evaluation, technical success for PTA/stenting was 96%. Long-term outcomes for secondary patency, limb salvage, and survival were the same in those treated percutaneously compared to those treated operatively. These outcomes hold true even for patients with complex lesions and long-segment occlusions.¹³³

LOWER EXTREMITY ARTERIAL INTERVENTIONS

Lower extremity atherosclerotic disease affects a substantial portion of the population. For a more in-depth discussion on the pathophysiology and clinical presentation of the disease, please refer to Chapter 95. Patients presenting with disabling claudication and who have failed nonoperative therapy, or those patients presenting with limb-threatening ischemia, are considered for more invasive intervention. Treatment has traditionally been bypass grafting for femoral artery, popliteal artery, and tibial artery disease. With the development of improved angioplasty and stent technology, more and more endovascular procedures are being applied to infrainguinal arterial disease.

Femoropopliteal Angioplasty and Stenting

The approach to femoropopliteal artery interventions can proceed via one of three routes. The antegrade approach via an antegrade puncture of the ipsilateral common femoral artery is perhaps one of the most utilized approaches. Alternatively, a retrograde approach through the contralateral common femoral artery can be used, with the catheters and wires traversing the aortic bifurcation. A less frequently used

approach is via puncture of the ipsilateral popliteal artery. This approach is often used in patients who have had a failed attempt at an antegrade approach or in those who have severe stenotic or occlusive changes in the proximal part of the superficial femoral artery. Once arterial access is obtained, principles of wire access, balloon dilation, and stent placement (when necessary) are similar to those described for aortoiliac artery PTA and stent placement.

10 There have been mixed results reported for outcomes of patients treated with percutaneous balloon angioplasty of femoropopliteal artery stenosis. Initial technical success occurs in 88% to 93% of patients.^{134–138} Primary patency rates for femoropopliteal interventions have been reported as 43% to 58% at 1 year, 41% to 46% at 2 years, 38% to 41% at 3 years, and 26% to 38% at 5 years.^{134–139} Several factors have been shown to affect outcome of femoropopliteal angioplasty. The length of the lesion has a negative effect on long-term patency. Lofberg et al.¹³⁸ evaluated outcomes of 92 patients who underwent 121 PTA procedures. They reported a primary patency at 5 years of only 12% in those with occlusions longer than 5 cm and 32% in those with occlusions shorter than 5 cm. Similar results were found by Matsi et al.,¹³⁴ but they had some success with PTA of lesions up to 10 cm in length. Others have shown that treatment of patients with stenoses fared better than those with occlusions, and those with claudication fared better than those with limb-threatening ischemia.¹³⁶ The quality of outflow also affects outcome.¹³⁹ Due to the poor outcomes of femoropopliteal PTA, some argue that it should not be recommended as a first-line treatment in patients with infrainguinal occlusive disease but reserved for those who would not tolerate surgery or have no surgical options. Others, however, argue that it does not preclude surgery and may be a viable first option, reserving surgery for those who eventually fail PTA. Given the poor outcomes of PTA, few studies have attempted to evaluate whether the placement of a stent, either primarily or after failed PTA, would improve outcomes of endovascular procedures in the femoropopliteal arteries. Outcomes from many of these studies have not been shown to significantly improve patency rates. Primary patency rates for femoropopliteal artery stenting have been reported as 54% to 86% at 1 year and 29.9% to 48% at 3 years.^{140–143} Secondary patency rates at 3 years increase to 68.3%.¹⁴³ Complications during PTA and stenting of the femoropopliteal arteries include arterial disruption, thrombosis, distal embolization, and arterial dissection. Complications occur more frequently in this branch of the arterial tree as compared with the aortoiliac system, and half of these complications require operative intervention.

Another technique to revascularize the lower extremity in a percutaneous fashion is the use of percutaneous intentional extraluminal (or subintimal) angioplasty and recanalization. This method overcomes some of the problems associated with conventional PTA in that the subintimal plane that is developed has a smooth neolumen, which may be less prone to thrombosis. The technique was originally described in 1990 by Bolia et al.¹⁴⁴ This procedure is accomplished by using a wire to enter the subintimal space of a native artery proximal to an area of hemodynamic significant stenosis or occlusion. The wire is advanced in this plane past an area of severe disease and then reenters the true lumen. The channel is then enlarged by balloon angioplasty. In the femoropopliteal region it has been specifically applied to long lesions, greater than 10 cm in length. Initial technical success rate of the procedure has varied from 82% to 90%.^{145–148} Initial failure of the procedure is primarily due to inability to gain reaccess to the true lumen. Primary patency rates have been reported to be 27% to 62% at 1 year. Long-term patency rates are not known, and the application of this technique is controversial. It generally carries a low morbidity and may represent a mode of revascularization in patients with limb-threatening ischemia who do not have a surgical option.

Many failures of PTA and stenting are due to the development of neointimal hyperplasia leading to recurrent in-stent

stenosis. In an attempt to address this problem, stents covered with graft material have been placed. Saxon et al.¹⁴⁹ reported the largest experience as part of a U.S. multicenter prospective randomized trial of PTA versus PTA and expanded polytetrafluoroethylene-covered stents. The total number of patients treated was only 28, with 13 patients receiving PTA alone and 15 patients randomized to PTA and covered stent placement. At 2-year follow-up, primary patency in the covered stent group was 87%, whereas in the PTA-alone group it was only 25% ($p = 0.002$). Further investigation is certainly warranted into the application of this technology. In addition, drug-eluting stents are being investigated for the treatment of femoropopliteal disease. One such study evaluated the use of sirolimus-eluting stents.¹⁵⁰ Sirolimus acts as an anti-inflammatory and cytostatic antiproliferative agent that diminishes smooth muscle cell proliferation, which may prevent the development of neointimal hyperplasia. Duda et al.¹⁵⁰ reported on the outcome of 36 patients recruited for the participation in a randomized, double-blind, prospective trial evaluating drug-eluting stents versus uncoated stents in the treatment of femoropopliteal occlusive disease. The in-stent mean lumen diameter was significantly larger in the sirolimus-eluting stent group compared with the uncoated stent at 6 months. Long-term patency rates are not yet known, and further investigation with this stent, as well as others, is under way.

Alternatives to PTA and stenting have been developed for percutaneous intervention of the lower extremity arterial tree, specifically utilizing debulking technologies. These entail two main technologies: directional mechanical atherectomy and laser atherectomy. Mechanical atherectomy was originally used in the coronary circulation, but has recently found new applications to the lower extremity arterial tree. These devices use either a rotational blade or a “plane”-like device that shaves the atherosclerotic debris from the arterial wall (Fig. 87.9). Most of the results for these devices are presented in small retrospective series or registry data, with the primary

FIGURE 87.9. Radiographic picture of an atherectomy catheter within the superficial femoral artery. The “blade” (arrow) shaves portions of the atheroma, thus opening up the flow channel. The shaved atheroma is collected in the chamber of the catheter (solid triangular arrow). Multiple passes of the catheter are made to allow for a large enough flow channel and to remove the stenosis.

endpoint evaluated often being freedom from target vessel revascularization. Zeller et al.¹⁵¹ reported a 76% technical success rate with these devices (defined as obtaining <30% residual stenosis). Over half of these lesions, however, required adjunctive balloon angioplasty or stent placement. The majority of data, however, come from the self-reported multicenter *Treating Peripherals with Silver Hawk: Outcomes Collection (TALON)* registry.¹⁵² Similar to other series, there was a 74% technical success rate, but one quarter of patients required an adjunctive procedure. Freedom from target vessel revascularization was 80% at 12 months. Multiple lesions and increasing Rutherford stage were predictors of less favorable outcomes.

Lasers have also been used to treat peripheral atherosclerotic disease. Excimer laser technology uses photochemical energy, which is absorbed over a very short distance and potentially eliminates any heat generation. It is ideally suited for treating long, concentric, chronic occlusions that cannot be traversed by other means. Often, however, the bore size of the laser is small (2.5 mm) and thus almost always requires the use of adjunctive procedures once the lesion is traversed. Laser atherectomy has demonstrated usefulness in specific situations. Scheinert et al.¹⁵³ reported outcomes of its use in 318 patients with 411 chronic superficial femoral artery occlusions. Initial technical success was 83%, and all of these required an adjunctive PTA or stent. Primary patency at 1 year, however, was only 34%, but improved to a 76% secondary patency. While long-term data demonstrate its usefulness in maintaining patency, its use in crossing difficult, long, chronic occlusions appears to be beneficial.

Crural Artery Angioplasty and Stenting

Treatment of critical limb ischemia resulting from tibial vessel occlusion remains a challenge. In most situations, patients are elderly or have multiple comorbidities, which place them at high risk for surgery. Early application of angioplasty and stenting techniques to tibial vessel lesions was limited. With increased experience, however, the lack of emergent surgery to “rescue” tibial interventions has led to wider application. The technical aspects of the procedure do not differ too significantly from angioplasty in other arterial locations. Guide wire access is obtained across the lesion. Typically, a smaller guide wire is required such as one that is of 0.018 or 0.014 inches in diameter. Angioplasty is performed primarily, with stents rarely being placed as the risk of thrombosis is too great. Immediate technical success occurs in 87% to 92% of patients.^{154,155} Complications related to tibial PTA that subsequently require emergent surgical intervention only occur in 0.7% of patients.

The two largest series reported on the outcomes of tibial PTA were reported by Faglia et al.¹⁵⁵ in 2002 and by Dorros et al.¹⁵⁴ in 2001. Faglia reported on the outcomes of 191 tibial PTA procedures performed in patients with critical limb ischemia (rest pain or tissue loss). Clinical recurrence occurred in 7.3% of patients at a mean time to recurrence of 4.6 months. The majority of these recurrences were successfully treated with repeat angioplasty. Major amputation was required in only 5.2% of patients. Dorros reported on the outcome of 270 PTA procedures in patients with critical limb ischemia. Over a 5-year follow-up, only 8% required a subsequent surgical revascularization and only 9% required a major amputation. Survival, however, was only 56% at 5 years. In some centers, tibial PTA for isolated tibial lesions is being considered as the primary intervention prior to tibial artery bypass, particularly in patients with multiple comorbidities.

More recently, Giles et al.¹⁵⁶ reported the results of infrapopliteal angioplasty in 176 limbs from 163 patients. In this series, technical success was achieved in 93% of the cases. At 1 and 2 years primary patency was 53% and 51%, respectively, while freedom from secondary restenosis and reintervention was 63% and 61%, respectively. Patients with less severe and less

FIGURE 87.10. Venograms from a patient who presented with left common iliac vein thrombosis. After thrombolysis, areas of residual stenosis were placed in the left common iliac and external iliac veins. **A:** Balloon angioplasty of a stricture noted in the left external iliac vein. Note the “waist” depicting the stenosis that is being treated during the balloon angioplasty (arrow). **B:** Self-expanding stents were placed in the left common iliac and external iliac veins. Depicted is the deployment of the most distal self-expanding stent (arrow). **C:** Completion venogram shows resolution of the stenosis and excellent flow within the venous system.

extensive disease fared better than those with more extensive disease. As more experience is gained with this procedure, a better understanding of its outcomes and its potential applications will be attained.

VENOUS INTERVENTIONS

The pathophysiology of chronic venous disease is complex and generally results from a combination of contributing factors, such as reflux, as well as outflow obstruction. The application of angioplasty and stenting to the venous circulation is gaining increased popularity. In particular, it is being applied to the treatment of iliac venous outflow obstruction. The etiology of outflow obstruction may be secondary to previous iliac vein thrombosis or due to a primary cause of obstruction, such as May-Thurner syndrome. A more thorough discussion of venous disease is presented in Chapter 102. The technique of venous angioplasty and stenting is similar to that applied to the arterial system. Guide wire access is obtained across the area of stenosis and PTA performed to eliminate the obstruction. Placement of a stent is often necessary, and intravascular ultrasound can play an instrumental role in accurate placement (Fig. 87.10).¹⁵⁷

Raju et al.¹⁵⁸ reviewed the results of balloon dilation and stent placement for the relief of iliac vein stenosis in 304 patients with symptomatic iliac vein stenosis. Of these patients, 57% had symptoms that were also associated with symptoms attributable to reflux disease. Approximately half of the patients had stenoses due to nonthrombotic causes (i.e., May-Thurner syndrome), whereas the other half were postthrombotic in nature. Forty-four limbs required a reintervention because of restenosis of the treated segment. Primary and secondary patency rates at 24 months were 71% and 97%, respectively. Sixty-two percent of patients with venous ulceration had healing by 2 years, and after stent placement limbs that were free from swelling increased from 12% to 47%, and limbs that were free from pain increased from 17% to 71%. Treatment of patients with occluded iliac veins is technically feasible. In general, however, these procedures require the stenting of longer segments (mean length 22 cm) and multiple in-line stents (mean stents equal to three).¹⁵⁹

THROMBOLYSIS

Thrombolytic therapy is generally used to treat acute arterial or venous occlusions. There are a variety of agents that have been

used for thrombolytic therapy, including streptokinase compounds, urokinase compounds (UKs), and tissue plasminogen activator and its recombinant forms (rt-PA). These agents are all plasminogen activators, which do not directly degrade fibrinogen, but rather are trypsinlike serine proteases that have high specific activity directed at the cleavage of a single peptide bond in the plasminogen zymogen, converting it to plasmin. Plasmin is the molecule that then cleaves fibrin polymer, resulting in the dissolution of thrombus. In the majority of cases of peripheral vascular disease in which thrombolytic agents are used, it is delivered in a catheter-directed fashion. Access to the blood vessel is obtained either on the contralateral side or in an “upstream” location. Best results are obtained if the area of thrombosis can be crossed with an infusion wire or catheter and the thrombolytic agent delivered directly into the thrombus burden. Specialized catheters and wires, with multiple small side holes, have been developed to allow for this. Other techniques of thrombolysis include the delivery of low-dose continuous infusion, the delivery of high-dose graded infusion, or pulse spray infusion in which periodic forceful injection of the drug into the clot is performed. Progress is assessed angiographically on a regular basis until thrombolysis is complete or no further progress is attained. In cases of acute limb ischemia, thrombolysis can generally be applied safely only to patients with category I and IIa limb ischemia, as it takes several hours to attain lysis. Patients with more severe ischemia may not tolerate the delay in recanalization and thus may require more urgent surgical intervention.

There have been two major randomized trials evaluating the use of thrombolytic therapy for lower extremity ischemia: Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) and Thrombolysis or Peripheral Artery Surgery (TOPAS).^{160,161} In the STILE trial thrombolytic therapy was successful at restoring patency in 81% of bypass grafts and 69% of native arteries. One of the successes of thrombolytic therapy was that it reduced the extent of the planned surgical procedure in 55.8% of the patients. At 6-month follow-up, only 5.7% of patients undergoing thrombolysis required an amputation, whereas 17.9% of those randomized directly to surgery required one. In the TOPAS trial, complete lysis was obtained in 67.9% of patients. Of those treated with thrombolysis, approximately one third had underlying lesions treated percutaneously and avoided a conventional operation. Treatment was most effective in patients whose thrombosis was less than 14 days in duration.

The main risks associated with the use of thrombolytic therapy are an increased risk of bleeding. In the STILE and TOPAS trials, complications occurred at an incidence of 22% to 41% of

patients and included hemorrhage, distal embolization, and catheter-related problems. Life-threatening hemorrhage occurred in 6.2% of patients undergoing thrombolytic therapy in the STILE trial and in 12.5% of patients treated with thrombolytics in the TOPAS trial. The TOPAS trial did reveal that when aspirin and therapeutic heparin were withheld during thrombolytic therapy, the rate of intracranial hemorrhage was decreased from 5% to 0.5%. In addition, aggressive control of hypertension is also beneficial at decreasing the risk of intracranial hemorrhage.¹⁶² An analysis of data collected in a prospective, single-institution registry at the Cleveland Clinic Foundation revealed an overall complication rate of 55.9% in patients undergoing thrombolytic therapy for both arterial and venous disease. Complications rates were also analyzed according to the type of thrombolytic agent used (either UK or rt-PA). In patients receiving thrombolytic therapy for arterial disease, the complications reported were the development of a hematoma or pseudoaneurysm (30.6% UK vs. 57.7% rt-PA), any bleeding requiring a transfusion (11.9% UK vs. 18.7% rt-PA), and intracranial bleeding (0.8% UK vs. 1.6% rt-PA). Mortality rates were 2.9% for UK and 1.6% for rt-PA. For patients treated with venous thrombolysis, the complications reported were hematoma formation (18.4% UK vs. 28.6% rt-PA) and any bleeding requiring a transfusion (14.3% UK vs. 42.9% rt-PA). There were no cases of intracranial bleeding in patients undergoing venous thrombolysis.

To minimize the risks of thrombolytic therapy, several criteria have been universally accepted as contraindications to its use. Absolute contraindications include stroke or transient ischemic attack within the past 2 months, gastrointestinal bleeding within the past 10 days, and neurosurgery or intracranial trauma within the past 3 months. Relatively major contraindications include cardiopulmonary resuscitation within the past 10 days, major nonvascular surgery or trauma within the past 10 days, uncontrolled hypertension, intracranial tumor, and recent eye surgery. From a technical standpoint, the use of micropuncture needles and small catheters may decrease the risk of bleeding complications. Monitoring of laboratory values, such as fibrinogen levels, has been of no value in predicting which patients are at increased risk of bleeding.¹⁶³ In the presence of hemorrhage, heparin and thrombolytic agents should be discontinued. If necessary, thrombolytic agents can be reversed with cryoprecipitate, fresh frozen plasma, tranexamic acid, aminocaproic acid, or aprotinin. These interventions are rarely necessary as most thrombolytic agents have short half-lives, in the range of minutes.

SUMMARY

Endovascular therapy is an exciting field that offers an alternate modality of treatment to patients with a variety of peripheral vascular disorders. In most cases, the indications for the procedure are the same whether an open or endovascular option is being considered. The field of endovascular therapy continues to grow at a rapid pace and will continue to do so with the development of improving technologies. These improvements may, in the future, allow many procedures to attain clinical equipoise with open surgical procedures and in such instances may replace them. In cases in which this is not true, the endovascular interventions may remain the procedure of choice in high-risk patients.

CHAPTER 88 ■ VASCULAR INFECTIONS

G. PATRICK CLAGETT

KEY POINTS

- 1 Vascular infections are among the most challenging and difficult problems encountered by surgeons.
- 2 The overall incidence of clinically overt prosthetic infections varies according to anatomic site.
- 3 The majority of vascular prosthetic infections are initiated at the time of operation.
- 4 The principal organism responsible for infections of all implanted medical devices, including vascular prostheses, is *Staphylococcus epidermidis*.
- 5 The clinical presentations of vascular prosthetic infections can be protean and subtle, so that the diagnosis is difficult.
- 6 Imaging tests are important because the consequences of a missed diagnosis may be lethal.
- 7 The primary goals of treatment are to save life and limb, and this is best accomplished by eradicating infection by excision of all infected prosthetic material and vascular tissues combined with appropriate arterial reconstruction.

- 1 Vascular infections are among the most challenging and difficult problems encountered by vascular surgeons. Patients are often elderly, frail, desperately ill with multiple medical comorbid conditions, and unable to tolerate the extensive, complex operations usually required to treat the problem. Medical treatment based on specific antibiotic therapy is rarely successful when used alone, and complete resection and excision of all infected vascular structures are usually necessary to eradicate infection. Immediate restoration of blood flow to critical vascular beds by alternate anatomic routes or with replacement vascular conduits that minimize the risk for recurrent infection present additional challenges that tax the skill and ingenuity of vascular surgeons. Despite a great deal of progress in the treatment of vascular infections, morbidity and mortality remain among the highest of all vascular conditions.¹⁻³

VASCULAR PROSTHETIC INFECTIONS

Pathogenesis

- 2 Vascular prostheses are foreign bodies that can be primarily infected by contamination at the time of placement or secondarily infected after implantation by hematogenous, lymphatic, or contiguous spread of microorganisms. The overall incidence of clinically overt prosthetic infection varies according to anatomic site. Aortic prostheses confined to the abdominal or thoracic cavity rarely become infected; the incidence ranges from 0.5% to 2%.² The incidence is higher, from 2% to 6%, in proximal or distal anastomotic sites at the femoral level (e.g., aortofemoral or femoral-popliteal bypasses).⁴

Several features of the femoral area predispose to infectious complications. The groin is a relatively dirty area that is difficult to clean, and incisions placed in the groin are prone to infection and healing problems. Vertical groin incisions cut obliquely across the inguinal crease, tend to gape, and in obese patients lie buried in moist folds of skin. Furthermore, superficial inguinal lymph nodes are usually transected during exposure of the common femoral artery and, if not ligated, will bathe a vascular prosthesis in lymph fluid that may contain bacteria. Potential sources of prosthetic contamination in this circumstance include open, infected ischemic ulcers of a lower

extremity; gangrenous toes; and wounds in any other area drained by the inguinal lymphatics, such as the perineum and perianal area. Another factor implicating the groin wound in the etiology of vascular prosthetic infections is transient local ischemia during placement of an aortic cross-clamp, which may render the wound more susceptible to infection.

- 3 Most authorities agree that the majority of vascular prosthetic infections are initiated at the time of operation.^{2,3,5} Although direct proof of this tenet is difficult to obtain, the prevalence of *Staphylococcus epidermidis* among offending organisms suggests that skin contamination with the patient's own flora is an important mechanism.^{6,7} Mucosal colonization of nasal, oropharyngeal, and gastrointestinal sites are also potential sources of *S. epidermidis* and other coagulase-negative staphylococci bacteremia and contamination.⁸

The presence of *Staphylococcus aureus* and other nosocomially acquired bacteria is also common and points to environmental sources of contamination. Other intraoperative sources of contamination include intestinal flora when the gastrointestinal tract is entered or when operations, such as cholecystectomy, are performed concomitantly. Laminated thrombus lining the wall of aneurysms has been implicated as a source of contamination and, when cultured, yields bacteria in about 10% of specimens. *S. epidermidis* is the most common isolate.^{9,10}

Postoperative sources of vascular prosthetic infection include wound complications, urinary tract infections, and invasive line sepsis. Early and late hematogenous seeding of prostheses can occur during transient bacteremia associated with remote, noncontiguous infections or dental procedures.

Although bacteria are most often cultured from infected arterial prostheses, other, less common microorganisms, such as fungi, *Mycoplasma*, and *Mycobacterium*, have been encountered. *S. epidermidis* is the most common pathogen reported in modern series and outnumbers *S. aureus* infections two to one. Gram-negative and polymicrobial infections are increasingly encountered, but remain less prevalent than gram-positive infections. In many cases, negative cultures are reported despite convincing local evidence of infection, including a nonincorporated prosthesis surrounded by grossly purulent fluid.¹¹ These cases are most likely due to *S. epidermidis* or other low-virulence organisms that are exposed to perioperative antibiotics at the time of sampling and require fastidious microbiologic techniques for growth. Sonication of infected prosthetic material, growth in tryptic soy broth, and prolonged incubation for

several days have been reported to increase the yield of cultures positive for *S. epidermidis*.¹²

The presence of a foreign body, such as an implanted device, increases the risk for infection. Early investigations documented that it takes only 10^2 *S. aureus* organisms to cause an abscess at the site of a subcutaneous silk suture, but 10^6 organisms to cause an infection in normal skin with no foreign body present. The explanations of why foreign materials are prone to infection involve physicochemical properties of the material, impairment of host defenses, and special properties of bacteria that facilitate their growth in the presence of a biomaterial.¹³

The biologic reaction to an implanted vascular prosthesis consists of an acute inflammatory response in the early stages and progresses to formation of a fibrous capsule or tissue growth into porous materials. Neutrophils rapidly become associated with any implanted biomaterial in vivo, become prematurely activated by contact with the material, and rapidly lose the capacity to become activated in response to subsequent stimuli, such as the presence of bacteria. Neutrophils in contact with biomaterials rapidly lose their ability to produce superoxide and other reactive oxygen species and become relatively impotent in their microbicidal activity.^{14,15} In a sense, the biomaterial becomes a massive “decoy” that averts and diverts the ability of neutrophils to respond normally to bacteria in the microenvironment. In addition, neutrophil products released in these circumstances may promote dysfunction of new neutrophils entering the microenvironment.¹⁶

Vascular prosthetic biomaterials may vary in their susceptibility to infection by different microorganisms. Highly textured or rough-surfaced biomaterials, such as textiles manufactured from Dacron (woven or knitted), are more prone to bacterial adherence than smooth-surfaced biomaterials, such as expanded polytetrafluoroethylene (ePTFE) or polyurethane.¹⁷ In vivo, adherence of platelets, plasma proteins, and other blood constituents and varying conditions of shear may dramatically alter the responses of different biomaterials to microorganisms, and all biomaterials remain susceptible to infection.^{18,19}

4 The principal organism responsible for infections of all implanted medical devices, including vascular prostheses, is *S. epidermidis*. It is one species of coagulase-negative staphylococci that is a major cause of nosocomial infections and of nosocomial bacteremias in particular.²⁰ The organism is a ubiquitous skin commensal of relatively slow growth and low virulence. It causes chronic infections with local manifestations, but little or no systemic toxicity. Pivotal in the pathogenesis of *S. epidermidis* infection is the production of multi-layered biofilms composed of exopolysaccharides, usually referred to as “slime.”

The elaboration of biofilms takes place following the adherence of *S. epidermidis* to biomaterials and usually occurs when organisms adhere to one another in microcolonies.²¹ Both adherence of organisms to polymer surfaces and to each other (cell–cell adhesion) is mediated by capsular polysaccharide adhesins.^{21,22} Mutant bacteria that do not produce adhesins lack cell–cell adhesion and do not produce biofilms.²³ Once elaborated, biofilms form a protective shield that allows continued bacterial growth in relatively hostile environments. Bacterial nutrients and metabolic wastes freely traverse the polysaccharide biofilm, but antibiotics do not. Biofilms also alter inflammatory changes, impair host defenses, and promote tenacious adherence of microbial colonies to the biomaterial.²⁴ *S. epidermidis* infections tend to be persistent and refractory to antibiotics, and the implant must be removed to clear the infection.

The phenotypic transformation of *S. epidermidis* to an indolent, low-virulence organism that produces a protective biofilm is due to a phenomenon known as quorum sensing.²⁵ Quorum sensing is the regulation of gene expression in response to fluctuations in cell density. *S. epidermidis* and other quorum-sensing bacteria release autoinducers or pheromones that vary

in concentration proportional to cell density. Oligopeptide autoinducers attach to cell surface receptors and induce transcriptional changes, resulting in dramatic changes in gene expression. In the case of *S. epidermidis*, organisms circulating alone (planktonic state) produce a low level of autoinducer in the microenvironment. Planktonic *S. epidermidis* organisms have aerobic metabolism and secrete multiple virulence and proinflammatory factors that produce signs and symptoms of sepsis. However, when these organisms attach to and aggregate in close proximity on polymer surfaces, quorum sensing results in the activation of multiple genes that result in a low-virulence organism that has anaerobic metabolism and produces abundant biofilm.²⁶ In addition, genes that are involved in the production of virulence factors are suppressed. In essence, the *S. epidermidis* microorganism goes into a kind of “hibernation.”

Once established, bacterial infection spreads throughout a vascular prosthesis and eventually involves anastomotic sites. The eventual destruction of vascular tissue leads to the formation of an anastomotic false aneurysm. The first manifestation of a vascular prosthetic infection is often an anastomotic false aneurysm or its most frequent complication, prosthetic limb thrombosis in the case of an aortobifemoral bypass. When the false aneurysm involves the aortic anastomosis, rupture into the duodenum may occur and produce an aortoduodenal fistula with catastrophic hemorrhage.

Although all microorganisms producing vascular prosthetic infections are associated with false aneurysms, they vary in their propensity to destroy vascular tissue. Gram-negative organisms, such as *Pseudomonas aeruginosa*, *Proteus* species, and *Escherichia coli* are particularly notorious for their ability to digest vascular tissue.²⁷ These organisms elaborate elastase and alkaline protease, which break down elastin, collagen, fibronectin, and fibrin. *S. epidermidis* and other coagulase-negative staphylococci also secrete proteolytic proteins that can degrade vascular tissue. The mechanisms underlying protease elaboration and activation are highly regulated and complex.²⁸ In addition to causing vascular disruption and the formation of false aneurysms, many bacteria produce substances that are highly thrombogenic and may induce thrombosis that is the first manifestation of a vascular prosthetic infection.

Clinical Presentation

5 The clinical presentations of vascular prosthetic infections can be protean and subtle, so that the diagnosis is difficult. The tempo and severity of the clinical manifestations often depend on the microorganism. A patient whose infection is caused by a virulent organism, such as *S. aureus*, *P. aeruginosa*, or *E. coli*, presents with systemic signs of sepsis. As an example, a patient with a vascular prosthesis who has persistent fever, chills, and an elevated white blood cell count with a left shift should be suspected of having a vascular prosthetic infection. Virulent microorganisms also tend to cause earlier manifestations of infection, with the interval between implantation of the prosthesis and diagnosis of infection often being months. Very early prosthetic infections, diagnosed within weeks of implantation, are most often associated with wound infections that involve the vascular prostheses by contiguous spread.

In contrast, patients with infection caused by a low-virulence organism, such as *S. epidermidis*, present later, often years after placement.⁷ Systemic signs and symptoms are usually mild or absent. These patients most often present with local manifestations, such as a chronic groin sinus that discharges small amounts of pus, a chronic wound infection exposing the prosthesis, femoral anastomotic false aneurysm, or aortofemoral bypass limb thrombosis. They may have low-grade fever and mild constitutional symptoms, but overt systemic signs of sepsis are absent. The white blood cell count is usually normal or only mildly elevated, but the erythrocyte sedimentation rate is often abnormal. A patient presenting with a femoral

ALGORITHM 88.1

ALGORITHM 88.1. Diagnosis and treatment of prosthetic infection.

anastomotic false aneurysm or limb thrombosis who has an elevated erythrocyte sedimentation rate should be suspected of having a vascular prosthetic infection.

Patients presenting with massive gastrointestinal hemorrhage from aortoduodenal or aortoenteric fistula frequently have had lesser episodes of bleeding hours to days before the major episode. These are often referred to as “herald” or “sentinel” episodes of bleeding and offer a window of opportunity for diagnosis and management that may avert exsanguinating hemorrhage. Any patient with an intra-abdominal vascular prosthesis who has an episode of upper or lower gastrointestinal bleeding should be suspected of having an underlying aortoenteric fistula, and an expeditious workup is important.

Chronic gastrointestinal bleeding can also occur in patients with an aortoenteric fistula, but is more often associated with an enteric erosion. This condition, often referred to as “graft-enteric erosion,” differs from aortoenteric fistula in that the body or limb of the vascular prosthesis erodes into bowel and the aortic suture line is not involved. This produces chronic bleeding from the eroded bowel mucosa, analogous to bleeding from an ulcer, and patients may present with chronic anemia. The diagnosis should be suspected in a patient with an intra-abdominal vascular prosthesis who has anemia, stool positive for occult blood on guaiac testing, and fever.

Another manifestation of aortofemoral and aortoiliac prosthetic infections is hydronephrosis. This can develop if the ureter becomes obstructed as a result of periprosthetic inflammation and may be bilateral or unilateral, depending on the extent of infection. It is unusual for hydronephrosis to be the initial manifestation of vascular prosthetic infection because the urologic condition is usually asymptomatic. This complication most often is noted during the workup of a patient with an infected vascular prosthesis who presents with other symptoms, such as a groin sinus or gastrointestinal bleeding.

Diagnosis

- 6** Because the manifestations of vascular prosthetic infections are so varied and subtle and because the consequences of a missed diagnosis may be lethal, imaging tests are important (Algorithm 88.1).²⁹ The types of imaging and other diagnostic tests used are based on the clinical presentation. Computed tomography (CT) scanning has long been the mainstay of diagnostic imaging for suspected vascular prosthetic infection. CT findings suggestive of infection include ectopic gas, periprosthetic fluid, loss of tissue planes, periprosthetic inflammatory changes, thickening of adjacent bowel, hydronephrosis, and anastomotic false aneurysm (Fig. 88.1).³⁰ These findings are most specific and useful for late infections. During the immediate period

following implantation, periprosthetic fluid, air, and inflammatory changes may be present for 2 to 3 months. After 3 months, postoperative hematoma and gas should resolve and tissue planes return to normal.³¹

Magnetic resonance imaging (MRI) has provided an alternative to CT scanning for cross-sectional imaging. In addition to demonstrating the same features seen on CT (periprosthetic air, fluid and structural abnormalities), MRI is particularly helpful in assessing periprosthetic inflammatory changes. These are seen as high-intensity signals on T2-weighted images in the tissues surrounding the prosthesis and accurately portray tissue edema (Fig. 88.2).³² Such images can be particularly helpful in assessing the extent of infection, which may determine the operative approach. For example, in a patient with an infection localized to a single, distal limb of an aortobifemoral bypass, removal of the entire prosthesis may not be required for adequate treatment of the infection.

Radionuclide scanning has also been used in the diagnosis of vascular prosthetic infections. Scintigraphy with the use of autologous white blood cells labeled with indium oxine ¹¹¹In is the most common technique currently used, although the use of white cells labeled with ⁶⁷Gallium, technetium, and other isotopes have been reported.^{33,34} In addition, scintigraphy based on labeled human immunoglobulin G has been used and may be more sensitive than scintigraphy with white blood cells.³⁵ Most recently, positron emission tomography (PET) imaging has been found to be useful in imaging graft infection.

FIGURE 88.1. Computed tomography (CT) scan of lower pelvis demonstrating fluid and an enhancing ring around the left limb of an aortobifemoral bypass (arrow).

FIGURE 88.2. Magnetic resonance imaging (MRI) of the lower pelvis of the patient in Figure 88.1. The arrow points to high-intensity signals on T2-weighted images characteristic of inflammation and tissue edema.

Increased levels of fluorodeoxyglucose (FDG) tagged with isotope may be seen in areas of activated granulocytes. FDG-PET appears to have greater sensitivity and specificity in the diagnosis of graft infections in comparison to other imaging modalities.³⁶

A problem with all scintigraphic methods in diagnosing vascular prosthetic infections is a lack of specificity caused by uptake in other organs or tissues that may be contiguous. In addition, faint or no uptake in the presence of limited or low-virulence infection can result in false-negative results. Scintigraphy is most helpful when occult prosthetic infection is suspected. An example would be a patient with a vascular prosthesis presenting with a fever of unknown origin or a complex of other nonspecific symptoms in whom white blood cell scintigraphy “lights up” the prosthesis.

Ultrasonography can be useful and is noninvasive and inexpensive. The finding of an echo-lucent rim or “halo” sign surrounding a vascular prosthesis is highly suggestive of a vascular prosthetic infection³⁷ (Fig. 88.3). In addition, duplex ultrasonography may uncover other findings such as anastomotic false aneurysms that are frequently associated with vascular prosthetic infections.

FIGURE 88.3. Duplex, color-flow scan demonstrating echo lucent rim or “halo” sign surrounding the limb of an aortofemoral bypass graft.

Arteriography is of limited usefulness in the diagnosis of vascular prosthetic infection, but it may, on occasion, demonstrate an aortic false aneurysm or even active leakage of contrast into the bowel lumen, which is pathognomonic for aortoenteric fistula. Arteriography is helpful in planning reconstruction after removal of the prosthesis and is most useful in late infection, when the vascular anatomy may have been altered by progressive occlusive disease.

In patients presenting with gastrointestinal bleeding and suspected aortoenteric fistula, complete upper gastrointestinal endoscopy with visualization of the third and fourth portions of the duodenum, the most common site of fistula, is necessary. Even if this study is incomplete, with inability to visualize the distal duodenum or the finding of gastrointestinal lesions (e.g., chronic peptic ulcer) that are not actively bleeding, an aortoenteric fistula may still be present. Continued, unexplained bleeding mandates operative exploration to rule out aortoenteric fistula. At the time of operation, the duodenum, proximal jejunum, and any other bowel in contact with a vascular prosthesis must be dissected free to make or exclude this diagnosis.

Treatment

7 The primary goals of treatment are to save life and limb, and this is best accomplished by eradicating infection and maintaining adequate circulation to portions of the body perfused by the infected prosthesis. Secondary goals include minimizing morbidity, restoring normal function, and maintaining long-term function without the need for repeated intervention and risk of amputation.

These goals are best achieved by excision of all infected prosthetic material and vascular tissues combined with appropriate arterial reconstruction. The currently favored methods of arterial reconstruction for aortic prosthetic infection include extra-anatomic bypass^{38–54} and in situ replacement with the use of autogenous femoral-popliteal veins,^{52,55–63} arterial allografts,^{64–76} and vascular prostheses that are often treated or soaked in antibiotic solutions.^{52,77–82} A recent meta-analysis of pooled data demonstrated several advantages of in situ graft replacement over extra-anatomic bypass.⁸³ In situ graft replacement is becoming increasingly popular because it is expedient, avoids an aortic stump with potential for lethal blowout, and is associated with a low amputation rate.

Pooled outcome data from contemporary series reported since 1985 are presented in Table 88.1. Direct comparisons of these data to judge the relative success of the various approaches are difficult because of the heterogeneity of patients with different degrees of illness and different comorbid conditions in the reported series. All of these approaches are valid and useful depending on patient-specific characteristics and circumstances. It is a mistake to think that a single surgical approach is applicable to all patients with this condition. These complicated and multifaceted patients with varying degrees of illness require individualized attention. The pros and cons of each approach are also outlined in Table 88.1.

Extra-anatomic bypass, usually involving an axillofemoral bypass, is an excellent choice for infected aortoiliac reconstructions in which femoral sites are free of sepsis and arterial runoff is good (Fig. 88.4). It is also possibly less of a physiologic insult than other procedures, particularly when the operations can be staged so that extra-anatomic bypass precedes removal of the infected aortic prosthesis by a period of days.³⁹ This approach has the advantage of preserving lower extremity blood flow during removal of the aortic prosthesis, so that ischemic time is minimized.

Unfortunately, the durability of an extra-anatomic bypass is limited in patients with multilevel occlusive disease and poor runoff. Most patients with infected aortic prostheses have an aortobifemoral bypass, and extra-anatomic bypass in such patients usually requires bilateral axillofemoral procedures

^aPooled data from major series reported since 1985.

FIGURE 88.4. Standard treatment for an infected aortic vascular prosthesis. An axillobifemoral bypass is performed first. This is followed a few days later by removal of the infected aortic prosthesis and careful oversewing of the aortic stump as illustrated. This operation has its greatest usefulness in patients with infected aortoiliac prostheses and who have femoral areas free of infection and good runoff.

with distal anastomoses to diseased and, often, small profunda femoral or popliteal arteries. These are disadvantaged reconstructions with poor long-term patency despite the administration of antithrombotic agents (Table 88.1). They are prone to sudden thrombotic occlusion without warning, and amputation rates are high, even after thrombectomy and multiple revisions. In one large series, one third of patients required major amputation during long-term follow-up.⁴⁰ In addition, reinfection of the extra-anatomic bypass prostheses occurs in 10% to

20% of patients, and this condition is often lethal. A final problem with extra-anatomic bypass is continuing infection at the site of aortic closure, or aortic “stump.” Although an infrequent occurrence (<10% of cases), aortic stump blowout is almost always fatal.

Dissatisfaction with the long-term patency of extra-anatomic bypass led to the development of in situ autogenous venous reconstruction.^{52,55–63} Early experiences were with greater saphenous veins, but the use of femoral-popliteal veins rapidly evolved because of their large caliber and superior patency (Figs. 88.5 and 88.6).⁵⁵ This reconstruction is most applicable in patients with extensive occlusive disease and poor runoff, a circumstance in which the patency of an autogenous venous reconstruction would theoretically be better than the patency of a prosthetic bypass. The situation is analogous to the use of vein grafts for femoral-popliteal and distal bypasses because of their superior patency in comparison with prosthetic conduits. This advantage has been realized, with excellent 5-year cumulative rates of 85% to 90% for primary patency and 100% for secondary/assisted patency in superficial femoropopliteal vein aortofemoral reconstructions.^{57,58,63} Long-term amputation rates have been reported to be correspondingly low.

The principal disadvantage of using femoral-popliteal veins for aortofemoral reconstruction is that the procedure is technically demanding and long. The lower extremity ischemic time is longer than with other approaches, but can be minimized by carefully sequencing the procedure to shorten aortic cross-clamp time. To minimize open body cavity exposure and lower extremity ischemia, the operation is carried out in the following order: (a) dissect femoral-popliteal veins and leave in situ until needed, (b) isolate and control femoral vessels, (c) enter abdomen and obtain aortic control, (d) remove infected prosthesis, and (e) perform reconstruction with femoral-popliteal veins.⁸⁴

Acute venous hypertension can result in the need for leg fasciotomy in up to 20% of limbs following harvest of the femoral-popliteal vein.⁸⁵ Special risk factors that predict the need for fasciotomy include preexisting, advanced limb ischemia (preoperative ankle-brachial index <0.40) and concomitant ipsilateral harvest of the greater saphenous vein. Acute muscle swelling from venous hypertension coupled with ischemia-reperfusion injury is a major pathogenetic factor.⁸⁵

Long-term lower extremity venous morbidity is also a potential drawback to harvesting the femoral-popliteal veins. However, venous morbidity has been surprisingly infrequent and mild.^{57,63} The benign course following removal of the femoral-popliteal veins is a consequence of several compensating mechanisms.⁸⁶ First, the junction of the profunda femoral

FIGURE 88.5. Multiple reconstructions using the superficial femoropopliteal vein after removal of an infected vascular prosthesis. **A:** Standard in situ aortobifemoral replacement. **B:** Left in situ aortofemoral bypass with left-to-right femoral crossover bypass. **C:** In situ aortoiliac reconstruction. **D:** Unilateral transobturator aorta profunda bypass. **E:** Femoral crossover bypass.

FIGURE 88.6. Lateral (A) and anteroposterior (B) arteriogram of a superficial femoropopliteal vein in situ replacement after removal of an infected aortobifemoral bypass. The left-to-right femoral crossover bypass with superficial femoropopliteal vein is not shown. The figure illustrates the excellent size match between the large-caliber superficial femoropopliteal vein and the infrarenal aorta.

and common femoral veins is carefully preserved after disconnection of the proximal femoral vein to allow unimpeded drainage via the profunda system. Second, several anatomic collateral connections are found between the remaining distal popliteal vein and the profunda system, and many of these collaterals enlarge to accommodate the increase in volume flow following removal of the femoral-popliteal vein. Finally, the valves in the tibial veins and collateral circuits remain functional, so that distal venous reflux does not occur.⁸⁷

A final concern is that placing femoral-popliteal veins in an infected field may lead to reinfection and disruption. Experience with this approach has documented that these vein grafts resist gram-positive, gram-negative, and fungal infections, and disruption of anastomoses has been rare. In a recent large series of in situ graft replacement for infected aortic prostheses, the overall incidence of graft disruption was 5%.⁵⁸ Most were in reconstructions for aortoenteric erosion or fistula where there was breakdown of the duodenal repair. Previous experience has documented that femoral-popliteal vein graft disruption usually occurs in settings where there is ongoing contamination of the graft, severe malnutrition, immunosuppression, and a debilitated patient.⁸⁸

Vein graft stenosis of femoral-popliteal grafts requiring endovascular or open surgical intervention is rare, occurring in approximately 5% of patients on long-term follow-up.⁸⁹ Special risk factors for vein graft stenosis include small-caliber graft (<6 to 7 mm in diameter), heavy smoking history, and significant coronary artery disease. Long-term aneurysmal degeneration has also been studied for up to 10 years after placement of these vein grafts, and has not occurred.⁵⁷

In situ allograft replacement has been reported with varying degrees of success.^{64–76} Acute and delayed aortic allograft disruption has been reported and is a distinct limitation of using allografts in infected fields^{66,90} (Table 88.1). In addition, long-term deterioration leading to thrombosis and aneurysmal degeneration has been reported. Ready availability of allograft material is another limitation of this approach in situations in which emergency or urgent operations are often required.

Replacement of the infected aortic prosthesis with a new prosthesis has also been reported.^{52,77–82} Most often, the new prosthesis is soaked in an antibiotic solution, usually rifampin (60 mg/mL for 15 minutes), before implantation.^{79,80} This approach is most often successful in patients with limited infections of low virulence following aggressive débridement

of all infected vascular and surrounding tissues to create a clean field. Despite these precautions, the potential for reinfection is a serious drawback and patients treated in this manner require close and vigilant follow-up with frequent imaging studies such as CT or MRI. They also are usually treated with lifelong oral antibiotics.

In situ prosthetic and allograft reconstructions may be most useful in very ill and unstable patients and in those with actively bleeding aortoenteric fistulas. Expedient in situ replacement in these circumstances can be lifesaving and may be used as a “bridge” procedure, with definitive reconstruction (extra-anatomic or femoral-popliteal vein) carried out at a later date when the patient has been rendered fit for such a reconstruction.

Conservative approaches that do not involve removal of the infected prostheses have also been reported.^{91–96} These are based on aggressive drainage and débridement of infected tissues; intensive, culture-specific antibiotic therapy; meticulous wound care to achieve coverage of exposed prosthetic material; and coverage of exposed prosthetic material with muscle flaps. Conservative approaches are most appropriately used when infection is extracavitary and limited in extent, systemic signs of sepsis are absent, the virulence of the infecting organisms is low, and anastomotic sites are uninvolved.⁹⁴ Elderly and frail patients with multiple medical comorbidities who would most likely not survive conventional operations for aortic graft infection should be considered selectively for less invasive procedures.⁹⁵ Like those who have undergone in situ prosthetic replacement, these patients require close follow-up and indefinite oral antibiotic treatment.

If an infection involves only one limb of a bifurcated aortic prosthesis, the limb is usually resected.^{12,97–100} Revascularization is often carried out via obturator bypass or another prosthetic reconstruction performed in a clean field. Autogenous femoral-popliteal or greater saphenous veins have also been used for this purpose.⁹⁹ It is important that the extent of infection be assessed with imaging studies in addition to direct visual inspection. In the case of a unilateral femoral infection of an aortofemoral bypass, the general approach is to begin the operation by inspecting the intra-abdominal portion of the prosthesis. If the infection grossly involves the main body of the bifurcated prosthesis, complete removal is necessary. If the suspected limb is well incorporated and free of gross infection, division of the limb, closure of the tunnel, and obturator or

other extra-anatomic bypass are performed. The final portion of this operation is removal of the infected limb from below, with care taken to prevent cross-contamination of other, freshly placed incisions that have been closed.

Infection of Femoropopliteal/Distal Prosthetic Bypasses

In general, the management principles for infected infrainguinal prosthetic bypasses are similar to those for infected aortic prostheses. Excision of all infected prosthetic material and creation of a new bypass through clean tissue planes are optimal.¹⁰¹ Venous autografts are preferable to vascular prostheses because of the low risk of reinfection. Unfortunately, many of these patients have limited sources of adequate vein for a new vein graft bypass. Additionally, because of the limited anatomic area, cross-contamination and infection of a new prosthetic conduit are probable. In selected patients, it may be possible to couple removal of the infected lower extremity bypass graft with an endovascular intervention to revascularize and maintain viability of the limb. Endovascular treatment under these circumstances should probably avoid stenting procedures because of the possibility of infecting stents.

The overall mortality of patients undergoing operations for infected prosthetic infrainguinal bypasses approaches 20% and may be higher in patients undergoing limb salvage procedures.^{101,102} These considerations have led some experts to recommend excision of the infected prosthesis and amputation in circumstances in which the limb remains in jeopardy after removal of the infected prosthesis. The rate of major amputation is approximately 40%.^{101,102} If assessment with Doppler ultrasonography indicates that the limb remains viable (audible arterial signals present at the ankle level), removal of the infected prosthesis with vein patch closure of anastomotic sites is preferred. If only a limited portion of the prosthesis is involved, nonresectional, conservative measures have been successfully used.^{91,103} Results with this approach are best when virulence of the infection is low, sepsis is absent, and anastomoses are free of infection.

Prevention of Vascular Prosthetic Infections

The benefit of short-term antibiotic prophylaxis in preventing wound infections after vascular surgery has been demonstrated in randomized trials.^{104–106} Most often, a first-generation cephalosporin is administered intravenously shortly before operation, during operation if blood loss is extensive or the operation is prolonged, and 2 hours after operation. Evidence suggests that a more prolonged course, for up to 4 to 5 days after operation or until all invasive lines have been removed, may provide additional protection.¹⁰⁷ When patients have infected ischemic lesions of a lower extremity, culture-specific antibiotics should be administered perioperatively. Also, the use of more specific prophylactic antibiotic therapy should be considered in hospitals where certain organisms are prevalent, especially when exposure is increased by prolonged preoperative hospitalization.

Attention to intraoperative factors is also important in preventing vascular prosthetic infections. Patients undergoing repeated and emergency operations are especially prone to wound infections and present additional risks. Meticulous attention to hemostasis and avoidance of wound hematomas and seromas that can become secondarily infected are important surgical tenets that are often difficult to achieve in patients given anticoagulants during the operation and who are also taking antithrombotic agents, such as aspirin or clopidogrel. If possible, these agents should be discontinued 1 week before the operation. Ligation and control of the femoral lymphatics

FIGURE 88.7. Patient had an uneventful endovascular aortic aneurysm repair 1 year prior to teeth cleaning. Two weeks after teeth cleaning, he presented with high fevers, chills, back pain, and an elevated white cell count. Computed tomography scan with intravascular contrast demonstrates an infected aortic stent graft with retroperitoneal extension and psoas abscesses. On explant, the aortic stent graft grew *Streptococcus viridans*, the most common microorganism found in the oral cavity.

are also probably important technical features in preventing vascular prosthetic infections. Electrocautery of lymphatic tissue leads to coagulation necrosis of lymphatic vessels, but does not prevent extravasation of lymph fluid.

Patients undergoing aortic operations are prone to intraoperative hypothermia, and this condition has been shown to impair neutrophil function and increase the incidence of postoperative wound infection.¹⁰⁸ Maintenance of normal body temperature should be the goal during major vascular operations. Additional procedures on the gastrointestinal or biliary tract that may result in intraoperative contamination of a vascular prosthesis should be avoided unless the additional procedure is deemed necessary to avoid life-threatening postoperative complications. Hematogenous seeding of a vascular prosthesis is a continuing risk for as long as the prosthesis is in place. Dental work, procedures on the gastrointestinal and genitourinary tracts, and angiographic procedures should be carried out with the patient protected by prophylactic antibiotics (Fig. 88.7).

INFECTED (MYCOTIC) ANEURYSMS

Pathogenesis

In the late 19th century, Osler first used the term *mycotic* to describe the peripheral, infected aneurysms occurring in patients with bacterial endocarditis.¹⁰⁹ The beaded gross appearance of the multiple aneurysms in these patients resembled a fungus growth, hence the term *mycotic*. However, he delineated the pathogenesis to be destruction of the arterial wall subsequent to embolization of bacteria-laden material from the heart. In the era before antibiotics, the presence of such lesions indicated a malignant form of endocarditis because death was inevitable.

Mycotic aneurysms, as described by Osler, are now rare, and a more comprehensive term is *infected aneurysm* or *microbial arteritis*.¹¹⁰ Infected aneurysms encompass preexisting aneurysms that are secondarily infected by hematogenous

or contiguous spread and infections of the arterial wall that subsequently cause aneurysmal degeneration.¹¹¹ When the arterial wall is completely disrupted and a contained rupture is present, the aneurysm may be termed an *infected false aneurysm* or *pseudoaneurysm*. Currently, fewer than 10% of infected aneurysms are caused by bacterial endocarditis.¹¹²

It is difficult to infect the normal arterial wall during bacteremia, but such a mechanism has been postulated in severely immunocompromised patients. Special risk factors for microbial arteritis include long-term steroid use, chemotherapy for malignancy, severe alcoholism, chronic renal failure, and extensive radiation therapy.^{113,114} Such infections may be initiated by hematogenous spread of bacteria through the vasa vasorum. Much more common is infection of abnormal arterial walls with irregular luminal surfaces, to which microorganisms attach during bacteremia.¹¹⁰ Arterial wall defects and irregularities associated with infected aneurysms include atherosclerotic plaque, degenerative arterial aneurysms, and congenital abnormalities, such as aortic coarctation and patent ductus arteriosus. Host compromise, malnutrition, and advanced age are also seen in many of these patients.

Contiguous spread of infection is common in infected aortic aneurysms and is seen in such conditions as spinal osteomyelitis, pancreatitis, and retroperitoneal abscess associated with diverticulitis and other gastrointestinal and severe urinary infections.¹¹⁰ Trauma is becoming an increasingly common mechanism by which infected aneurysms develop; bacteria are introduced at the time of intra-arterial drug injection with contaminated needles (drug abuse)¹¹⁵ or the placement of arterial catheters for diagnostic and therapeutic interventions or for monitoring.¹¹⁶ Almost all infected arterial aneurysms associated with trauma are false aneurysms in which arterial wall continuity is lost.

In reports of infection of preexisting aortic aneurysms, gram-positive organisms predominate over gram-negative organisms and are present in about 60% of cases.^{110,117} Of these, *Staphylococcus* species are the most prevalent, with *S. aureus* being the most commonly encountered overall. Streptococci are also etiologic agents, with *Streptococcus viridans* being the most common subtype. In iatrogenic arterial infections associated with indwelling arterial catheters, methicillin-resistant *S. aureus* and other nosocomial organisms are being seen with increasing frequency.

Salmonella is the most prevalent organism associated with infection of a nonaneurysmal aorta.^{110,114,117,118} The diseased, plaque-ridden aorta has a unique susceptibility to *Salmonella* infections. *Salmonella choleraesuis* and *Salmonella enteritidis*, especially the subtype *Salmonella typhimurium*, account for more than half of reported cases of *Salmonella* aortitis.¹¹⁰

Gram-negative arterial infections are much more virulent than gram-positive infections, and arteries infected with gram-negative organisms are much more prone to rupture. Gram-negative organisms, such as *P. aeruginosa*, can elaborate alkaline proteinase and a variety of elastases that cause vascular wall neurosis.²⁷ In addition, many bacteria, both gram positive and gram negative, produce collagenases.^{119–121} Bacteria can also upregulate collagenases and metalloproteinases in inflammatory cells associated with aneurysms.¹²¹ Recent interest has centered on neutrophil elastase in the pathogenesis of aneurysms.¹²² According to this view, bacteria may play an indirect role, acting principally through the recruitment of acute inflammatory cells, which subsequently release neutrophil elastase.

Once the arterial wall is infected, rapid, focal, and progressive deterioration occurs. This process results in the characteristic saccular or multiloculated appearance of these aneurysms and often leads to locally contained rupture and the formation of a false aneurysm. In aortas without a preexisting aneurysm, infected aneurysms tend to occur in the posterior wall of the suprarenal or supraceliac aorta^{110,113,114} (Fig. 88.8). When a preexisting aortic aneurysm becomes secondarily infected, the infrarenal location is the most common site.^{117,123,124}

FIGURE 88.8. Infected aneurysm involving the posterior wall of the supraceliac aorta.

Clinical Presentation

The clinical presentation of an infected aneurysm depends on the virulence of the organism, the anatomic location, and the duration of infection. *Salmonella* aortic infections may appear after a febrile gastrointestinal illness. The presence of a tender abdominal aortic aneurysm in such a patient in association with continued fever and positive blood cultures strongly suggests this diagnosis. Infection of a preexisting aortic aneurysm may present as fever of unknown origin, malaise, or back and flank pain. Such patients are frequently debilitated, malnourished, and immunocompromised as the result of chronic illness, and the presence of an aortic aneurysm and positive blood cultures in this setting should arouse suspicion of an infected aneurysm. Chronic osteomyelitis or other retroperitoneal infectious processes contiguous to the aorta may also be present.

Infected aortic aneurysms are prone to rupture, even when small.^{117,118} They may have been unsuspected before rupturing, and the diagnosis of infection may not be obvious at the time of emergency operation.¹²³ The diagnosis should be entertained in a patient presenting with a ruptured aortic aneurysm who has a fever and an elevated white blood cell count, especially when the aneurysm is small (<5 cm in diameter). At operation, additional clues include the presence of chronically inflamed retroperitoneal tissues with indistinct dissection planes and a focal aneurysm with relatively normal aorta above and below the site. Gram stains of smears from involved tissues and thrombus may be diagnostic, and cultures should be obtained even if the results of Gram stains are negative.

In contrast to aortic and other central aneurysms, peripheral infected aneurysms are usually readily apparent and the diagnosis obvious. A painful, cellulitic, warm pulsatile mass over a major artery in a febrile patient is a common clinical presentation.¹¹⁵ An elevated white blood cell count and positive blood cultures are usual. The patient may have a history of

drug abuse, and inadvertent or deliberate arterial injection with a contaminated needle should be suspected.¹¹⁵ The common femoral artery is the most common site, and a prior history of arterial catheterization or the presence of an indwelling angiographic catheter or sheath for endovascular procedures is being increasingly seen.¹¹⁶ Many of these procedures require repeated angiography and manipulation during prolonged periods, and femoral arterial sheaths or catheters are left in place for access. This increases the opportunity for arterial infection, and the risk is proportional to catheter residence time. Femoral puncture closure devices may also be sources of infection.¹¹⁶

Diagnosis

Infected aortic aneurysms can be difficult to diagnose. Leukocytosis is sensitive, but not specific, for an infected aneurysm. Blood cultures are important but may be negative in as many as 50% of patients with an infected aortic aneurysm.¹¹⁰ Positive blood cultures in the presence of an abdominal aortic aneurysm should be considered evidence of an infected aneurysm until they are proven otherwise.

Radiologic studies are useful in confirming the diagnosis; CT and aortography are the most important tests.¹¹⁸ MRI may also be helpful. CT and MRI will demonstrate the aneurysm and may show perivascular retroperitoneal inflammation and edema. A contained rupture may be present and suggests the diagnosis. The presence of periaortic air along with inflammatory changes is diagnostic (Fig. 88.9). Arteriography may aid in the diagnosis but is most useful in planning arterial reconstruction. A saccular aneurysm in an otherwise normal-appearing vessel or a multilobulated aneurysm strongly suggests the presence of aortic infection (Fig. 88.10).¹¹⁰

Treatment

Although culture-specific antibiotic therapy is important in the treatment of an infected aneurysm, surgical therapy is almost always necessary and lifesaving. Antibiotic therapy is started preoperatively and continued for at least 6 weeks after operation.¹¹³ Surgical treatment must be expeditious because of the risk for aneurysm rupture and death. In stable patients who are dramatically improving on antibiotic therapy, withholding surgical treatment for a period to minimize, and possibly eliminate, local infection may be appropriate. However, there are

FIGURE 88.9. Computed tomography scan of infected aortic aneurysm with gas (arrow) present within the aorta and adjacent soft tissue.

FIGURE 88.10. Computed tomography (CT) angiogram demonstrating focal, saccular infrarenal aortic aneurysm infected with *Staphylococcus aureus* in a human immunodeficiency virus-positive patient.

reports of rupture during prolonged antibiotic therapy and the timing of operative intervention is a matter of careful judgment.¹¹⁰

The principles of treatment for an infected aneurysm are similar to those of surgical therapy of an infected arterial prostheses: eradication of infection by resection of the infected aneurysm and surrounding tissues and creation of a new bypass to restore circulation. Most authorities favor creating a new bypass through clean tissues. For infected aortoiliac aneurysms, axillofemoral bypass is most commonly performed.^{112,114,118,123–125} For infected femoral aneurysms, an obturator bypass from the common iliac to the distal superficial femoral artery with a vascular prosthesis or vein graft routed through the obturator foramen successfully avoids the infected groin and restores distal circulation (Fig. 88.11).^{115,116}

Prosthetic reconstruction in situ has been successfully used for infected aortic aneurysms when gross purulence is absent and contamination is minimal.^{113,117,124,126–129} It is especially appropriate in patients with an aortic aneurysm that ruptures into the overlying duodenum, a condition usually referred to as *primary aortoduodenal fistula*. Contamination is minimal in this condition, and long-term results with prosthetic reconstruction in situ are good.^{117,126–130} Patients treated in this manner require close follow-up because of the risk for recurrent infection, and most should be treated with lifelong oral antibiotics. Prosthetic reconstruction in situ is usually necessary for unstable patients with ruptured, infected aortic aneurysms.¹¹⁷ Extra-anatomic bypass is not feasible in this circumstance because of the prolonged lower extremity ischemia time, especially when hypotension has been present. Overall mortality for patients with an infected aortic aneurysm is approximately 25% and is higher when rupture is present.¹¹⁰

A promising new approach involves harvesting femoral-popliteal veins to reconstruct the aortoiliac system after resection of an infected aneurysm and débridement of retroperitoneal

FIGURE 88.11. Extra-anatomic bypass options using superficial femoral-popliteal vein grafts for restoring lower extremity circulation for treatment of infected femoral aneurysms.

tissues.⁵⁷ These vein grafts have also been used to replace infected common femoral arterial aneurysms associated with drug abuse^{115,116} (Fig. 88.11). The large vein grafts appear to be resistant to infection by most organisms, and disruption when they are placed in infected fields is rare. Because of the additional operative time for harvesting veins, reconstruction in situ with femoral-popliteal veins should be used in relatively stable patients.

There are reports of endovascular aortic stent graft placement to exclude and treat infected aneurysms. However, contamination of the stent graft with resultant graft infection is a major drawback to this approach. Stent graft treatment of patients with infected aneurysms should be reserved for only the most desperately ill patients with ruptured, infected aneurysms. Even in these individuals, stent graft treatment should be considered a “bridge” in anticipation of definitive treatment when the patient stabilizes.

SEPTIC THROMBOPHLEBITIS

Septic thrombophlebitis most commonly involves upper extremity and neck veins after the insertion of intravenous catheters and needles or intravenous drug abuse. However, venous thrombi can become secondarily infected during bacteremia or contiguity with areas of infection. Examples of contiguous infection include pelvic septic thrombophlebitis developing after obstetric infections,¹³¹ internal jugular thrombophlebitis associated with severe pharyngitis and peritonsillar abscesses,¹³² and visceral thrombophlebitis stemming from appendicitis. *S. aureus* is the most common organism cultured from patients with peripheral septic thrombophlebitis, and gram-negative and polymicrobial infections are common when a contiguous infection is the cause. Regardless of the source, infected thrombus propagates throughout the lumen of the involved vein, and septicemia with high spiking fevers and chills quickly develops. An intense perivascular inflammatory response accompanies the spread of intraluminal infection and is clinically manifested by marked edema, pain, tenderness, and erythema overlying the involved vein. *S. aureus* and other virulent organisms infecting clot can rapidly form an intravascular abscess. In this circumstance, the lumen of the vein becomes a “closed space,” and excision or surgical drainage is necessary to treat the infection. Propagation of the infected clot

can also give rise to septic pulmonary embolism resulting in pneumonia, metastatic pulmonary abscess, and septic pleural effusion.

The clinical diagnosis is readily apparent when peripheral veins in the extremities are involved. In addition to pain, swelling, and redness along the course of the vein, pus may be expressed at the site of catheter or needle insertion. When deep or central veins are involved, the diagnosis is more difficult. These patients may present with clinical signs of severe sepsis and occasionally with complications of septic pulmonary embolization. CT or MRI can be particularly helpful and may demonstrate enlarged, dilated veins with intravenous thrombus and perivascular inflammatory changes. These imaging modalities are most useful for septic thrombophlebitis involving iliofemoral, caval, axillary-subclavian, and pelvic veins.

The treatment of septic thrombophlebitis depends on its anatomic location. Along with antibiotic therapy, excision of a superficial vein in an extremity is curative.^{133–135} One must take care to remove the entire length of involved vein to eradicate infection. When deep veins of an extremity or central veins of the chest or pelvis are involved, vein excision is difficult and associated with large losses of blood and severe morbidity. The mainstays of therapy for septic deep or central vein thrombophlebitis are intensive antibiotic therapy and heparin anticoagulation to halt the thrombotic process and prevent embolization.¹³⁶ Therapy may have to be continued for 2 to 3 weeks and is successful in most cases. If it is not successful and sepsis continues despite medical therapy, surgical intervention is indicated. Venous thrombectomy and vein excision have been reported to be successful in cases refractory to medical therapy.¹³¹ When thrombectomy of the ilio caval system is undertaken, placement of a stainless steel caval filtration device (Greenfield filter) for protection against pulmonary embolism may be advisable.¹³⁷ Sepsis does not preclude placement of these devices. In advanced cases in which abscess forms within large veins that cannot be subjected to thrombectomy because of organization of thrombus and vein scarring, abscess drainage and débridement are indicated.

CHAPTER 89 ■ **ATHEROSCLEROSIS AND THE PATHOGENESIS OF OCCLUSIVE DISEASE**

ANTON N. SIDAWY, ROBYN R. MACSATA, MATTHEW A. GOETTSCH, NITEN SINGH, AND SUBODH ARORA

KEY POINTS

- 1 Susceptibility to atherosclerosis might be determined by both intrinsic (numbers of intimal masses) and extrinsic factors (hypercholesterolemia, hypertension, diabetes, cigarette smoking).
- 2 The initial event might be the accumulation of lipid by insudation in regions of increased susceptibility. This would lead to the production of macrophage chemotactic factors and the influx of monocytes from the blood that together with the smooth muscle cells (SMCs) would sequester lipid and become foam cells.
- 3 Low-density lipoprotein oxidized in the wall, as well as other extrinsic injurious agents, could produce some degree of endothelial injury and perhaps later even limited denudation. Growth factors might then be released from the endothelium, activated macrophages and other leukocytes, and the SMCs, as well as from adherent platelets.
- 4 Growth factors could then stimulate proliferation and migration of susceptible SMCs to form isolated smooth muscle clones and fibrous lesions.
- 5 Further production of matrix by the smooth muscle would permit continued accumulation of lipid.
- 6 Like a growing tumor, these fibrous lesions would enlarge, develop ischemic cores, and thereby induce an angiogenic response.
- 7 The thickened plaque with its necrotic lipid core (the atheroma) might not withstand the rigors of continued arterial pulsation and might develop hemorrhage within the lesion on account of the shearing forces on the new capillaries.
- 8 Breakdown of the surface and a change in the coagulation function of the endothelium would render the plaque more thrombogenic. Such changes would lead to the terminal thrombotic event, the hallmark of all ischemic complications in atherosclerotic patients.

Atherosclerosis is a disease of the intima of large arteries that causes luminal narrowing, thrombosis, and occlusion associated with ischemia of the end organ. Throughout much of its course, the disease is not detectable. Thrombosis, including vascular occlusion and embolization, produces the clinical events of importance, such as myocardial infarction, stroke, and ischemic gangrene of the extremities. The widespread prevalence of lesions in arteries of asymptomatic people, the chronicity of the process, the suddenness of the terminal vascular events, and the lack of a single etiologic factor make it impossible to give a simple explanation for atherogenesis and atherosclerosis progression. In fact, atherosclerosis might be a form of nonspecific adaptation on the part of large blood vessels to a variety of harmful stimuli and the clinical consequences, or what we might call the true disease process, appear when the compensatory mechanisms are overwhelmed.

NORMAL STRUCTURE OF BLOOD VESSELS

Normal arteries and veins, both large and small, are formed from endothelium, smooth muscle, and extracellular matrix synthesized by these vascular wall cells. The vascular wall is invariably organized into layers (Fig. 89.1). The intima, defined as the part of the wall between the blood and the internal elastic lamina, is composed of a monolayer of endothelium at the luminal surface and may overlie one or more layers of smooth muscle. The media, lying beneath the intima, constitutes the bulk of the vessel and contains smooth muscle cells arranged in layers and dispersed in a matrix made of elastin, collagen, and proteoglycan. The adventitia lies outside the

external elastic lamina and forms the outer coat. It is composed of loose connective tissue, fibroblasts, capillaries, neural fibers, and occasional leukocytes. In very large arteries with greater than 28 elastic layers, a microvasculature (vasa vasorum) penetrates the media from the adventitial side and provides an alternative nutrient supply to the flux from the luminal surface.¹ Atherosclerotic lesion formation is associated with the proliferation of vasa vasorum at the site of lesion formation.² In thickened, atherosclerotic vessels the vasa vasora are extensive and penetrate into the diseased intima.^{3,4}

EMBRYOLOGY

In the fetus, the vessel wall is derived from mesoderm. A brief review of this process is of interest because many aspects of wound healing and atherogenesis in adult vessels represent a recapitulation of the fetal program of vasculogenesis and angiogenesis. The earliest vascular primordia in the embryo are isolated “hemangioblasts” that display endothelial and hematopoietic immunologic markers.^{5,6} The hemangioblasts cluster and form cords and, later, tubes that become the major vascular conduits. Some of the clusters become blood islands, the precursors for hematopoietic tissues. These structures sprout, grow, and remodel to form the primitive vascular system.⁷

Endothelial cells probably play a central role in the organization and building of vascular structures. They are derived from the hemangioblasts, organize at sites of later vessel development, and are followed by local mesenchymal cells that form the outer layers of the emerging blood vessels. These mesenchymal cells are the precursors of smooth muscle cells (SMCs) and fibroblasts. Once associated with the vessel wall,

FIGURE 89.1. The artery wall is made of multiple layers (intima, media, and adventitia) that vary in composition depending on the artery.

many of these cells begin to express smooth muscle–specific α actin. SMCs recruited to developing coronary arteries are derived from a unique progenitor population within the proepicardial organ. These cells are distinct from cells recruited to coat peripheral arteries. SMCs recruited to the wall of the developing arch and great vessels are thought to derive from neural crest cells, and those of the more distal aorta and visceral and lower extremity arteries are recruited from adjacent mesenchyme.⁸ This pattern of endothelial invasion followed by smooth muscle recruitment is reactivated in later life during angiogenesis in the presence of tumors and in wounds undergoing repair.

The adult form of blood vessels appears to be established by birth. In large vessels, the number of elastic and smooth muscle layers remains constant, although wall mass increases due to smooth muscle proliferation and matrix synthesis.^{9,10} The vascular architecture is probably genetically determined because alterations in animal size by hormonal manipulations (e.g., excess growth hormone) are associated with increased wall mass but no change in the number of cell layers.¹¹ It is likely that the primitive endothelial cell regulates wall architecture because it is involved in the recruitment of the corre-

sponding primitive SMC. These activities of the endothelial cell in the embryo presage its role in determining vascular diameter and mass in normal and diseased adult arteries.

These observations on the embryologic origin of vascular wall cells and the development of blood vessels provide many insights into vascular wall organization and function in the adult and provoke numerous questions for which at present there are few answers. In the last decade, the answers to these questions and a rudimentary understanding of how vascular cells interact in normal and disease states have begun to be realized. In the next section, recent evidence that vascular wall function and structure depend absolutely on cell–cell interactions is reviewed.

REGULATION OF LUMINAL AREA

This description of the usual arterial wall anatomy gives no clue to how a vessel adjusts its mass and dimensions in response to external stimuli (hypertension, increased blood flow, vascular injury) or to how it maintains a nonthrombotic state at the luminal surface. For this, the array of possible

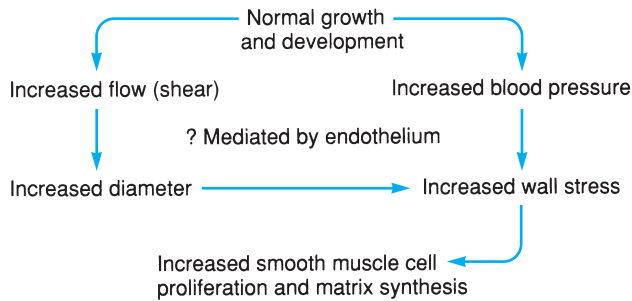

FIGURE 89.2. Changes in blood flow and pressure can have profound effects on arterial wall structure. In part, the response to hemodynamic changes might be mediated by the endothelium. (Adapted from Clowes AW. Theories of atherosclerosis. In: White RA, ed. *Atherosclerosis and Arteriosclerosis: Human Pathology and Experimental Animal Methods and Models*. Boca Raton, FL: CRC Press; 1989:3.)

physiologic functions of the wall and its cellular components under normal and abnormal conditions must be considered.

Blood vessels, both large and small, become larger during growth and development and as a compensatory mechanism to increased blood flow or, more appropriately, increased blood velocity (Fig. 89.2). A particularly striking example of this is found in an artery proximal to an arteriovenous fistula; if the fistula is not treated, the artery can become frankly aneurysmal.¹² Similarly, a vessel undergoing stenosis experiences an increase in blood velocity at the point of luminal narrowing. When the stenosis is attributable to intimal thickening or to an atherosclerotic plaque, the vessel dilates at the site of the lesion. For example, a diseased coronary vessel dilates and can maintain the correct luminal dimensions despite changes in wall structure as long as the intimal lesion does not occupy more than 40% of the area inside the internal elastic lamina (Fig. 89.3).¹³ At this point, pathologic narrowing begins to take place. Why vessels should dilate in each of these instances when the velocity of flow increases has not been determined. One possibility is that the cells in the wall, particularly the endothelium, are somehow capable of sensing changes in blood velocity and shear and can translate this biomechanical information into biochemical signals that then regulate the contractile state of the artery.^{14–17} The effect of shear stress on the regulation of arterial vasomotility is described in more detail later in this section. Endothelial cell secretory products play a critical role in SMC function.¹⁸ Endothelial cells secrete vasodilating (prostaglandin I₂ and E₂, adenosine, and nitric oxide) and vasoconstricting substances (endothelin). Where endothelium is damaged or absent, adherent platelets release the vasoconstrictor thromboxane A₂.

Nitric oxide (NO), previously called endothelium-dependent relaxing factor, is an important regulator in normal and diseased vessels.¹⁹ It is a short-acting substance that is derived from the metabolic breakdown of arginine.^{20–22} It is synthesized by nitric oxide synthase (NOS) by the oxidation of L-arginine. NO regulates vascular tone, downregulates endothelin, increases SMC apoptosis, and decreases SMC proliferation.²³ A number of factors stimulate endothelial cells to secrete NO, including thrombin, acetylcholine, bradykinin, serotonin, and products of platelet release. More recently it has been shown that shear stress, cyclic strain, and repetitive deformation consistently induce NO directly or increase NOS levels from vascular cells.²⁴ Hence, when the endothelium is present and functional, neighboring thrombotic events are likely to cause vasodilation, whereas when the endothelium is absent or dysfunctional, these same factors cause vasoconstriction. In addition, endotoxin lipopolysaccharides are a potent NOS inducer, resulting in pathologic NO production. Moreover, when the endothelium is missing, the vessel does not respond

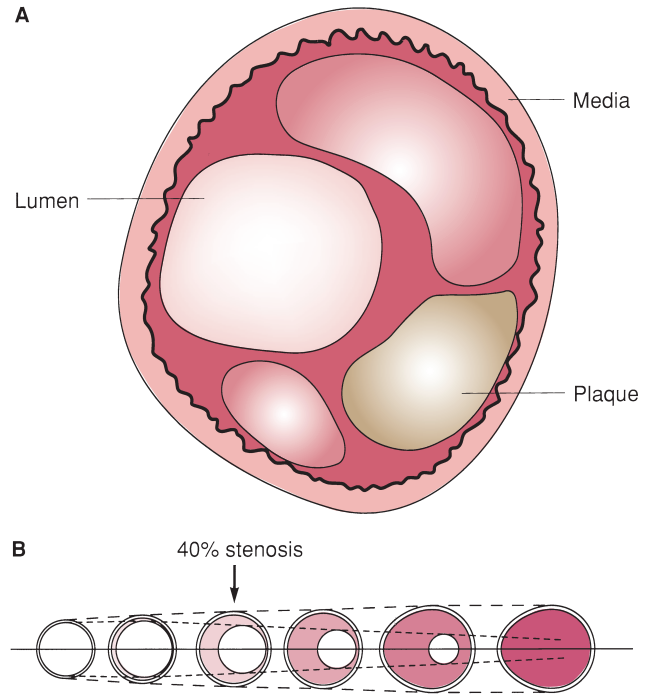

FIGURE 89.3. A: Coronary arteries dilate as atherosclerotic plaques form and maintain normal luminal dimensions. Luminal narrowing begins only after the plaque occupies more than 40% of the cross-sectional area within the internal elastic lamina and bulges outward at sites of medial atrophy. B: The course of lesion formation and luminal narrowing. (Adapted from Glagov S, Weisenberg E, Zarins CK, et al. Compensatory enlargement of human atherosclerotic coronary arteries. *N Engl J Med* 1987;316:1371.)

normally to changes in blood flow, either in the short term or the long term.²⁵ Changes in blood flow affect wall mass.^{26–28} In this regard, it is interesting to note that various factors that affect smooth muscle contraction or relaxation also modulate growth (NO, endothelin, thrombin, and prostaglandins).^{29–33} These observations may be the first preliminary evidence that transient signals affecting the diameter of vessels might have, in the long term, more permanent effects on wall structure. Certain pathologic conditions in which endothelium either is missing or is abnormal are associated with acute and chronic vasospasm; it is quite possible that the acute problems of atypical angina (coronary vasospasm) and cerebrovasospasm after cerebral hemorrhage are manifestations of abnormal endothelial function and decreased NO.³⁴ There is a relationship among shear stress exerted on the arterial lumen, the production of NO, and the development of atherosclerosis. Normal shear stress in arteries (usually >15 dynes/cm²) is protective, whereas low shear stress (<4 dynes/cm²) induces the formation of atherosclerotic lesions.³⁵ In addition, Malek et al.³⁶ have found that increasing shear stress led to an increase in the expression of endothelial NO synthase (eNOS) mRNA, leading to an increase in NO production, resulting in vasodilation. Areas of low shear stress in the arterial tree, such as the carotid bifurcation, are foci for the formation of atherosclerotic lesions.³⁵

Endothelial dysfunction underlies and is the earliest change in the development and progression of atherosclerosis. This role of endothelial dysfunction has been emphasized recently. It probably begins in childhood and extends through clinical events later in life. Most studies have shown that impaired endothelial function exists very early in the development of atherosclerosis, before the appearance of visible lesions. In children of parents with genetic defects of lipid transport or in

children living with smokers, there is clear evidence of endothelial dysfunction. As these children grow, the endothelial dysfunction becomes more pronounced, and it continues to exist after atherosclerosis is established.³⁷ It is present in numerous conditions associated with an increased risk for cardiovascular disease including hypertension, hypercholesterolemia, cigarette smoking, diabetes mellitus, and estrogen deficiency in postmenopausal women.³⁸

The endothelium is a very active organ. Endothelial cells have the ability to transduce signals from the flow of blood and from chemicals and then to convert these signals into actions in the underlying vessel wall. The surface of endothelial cells has a wide variety of receptors, including those for shear stress, oxidized low-density lipoproteins (LDLs), and inflammatory mediators, to name a few. Through these receptors, endothelial cells orchestrate actions that affect not only the endothelium, but also the entire vascular wall. In diseased state, such actions include adverse changes in vascular tone, proliferation of SMCs resulting in hypertrophy, and recruitment and adhesion of mononuclear cells, which are early steps in the development and progression of atherosclerosis. One of the most important defenses that the endothelium possesses for maintaining vascular health is NO, which has been shown to inhibit the expression of receptors that mediate substances implicated in the formation of atherosclerosis, such as oxidized LDL, inflammatory mediators, and angiotensin II.³⁹ In addition, NO prevents platelet aggregation and platelet adhesion and leukocyte chemotaxis.²³

The chief role of NO in reversing pathologic changes appears to be its ability to counteract oxidative stress, a common pathogenic pathway for most major risk factors for atherosclerosis. Reduced eNOS may be the result of reactive oxygen species (ROS) that form peroxynitrite, which leads to oxidation of LDL and DNA injury. Peroxynitrite is known to cause accelerated SMC apoptosis and to play a significant role in vascular remodeling. Peroxynitrite and subsequent DNA injury activate poly(adenosine diphosphate [ADP]-ribose) polymerase (PARP), a nuclear enzyme that is involved in DNA damage repair and cell death via the necrotic route. PARP also regulates the release of the mitochondrial cell death factor, apoptosis-inducing factor (AIF), in cardiac myocytes during oxidative stress. AIF appears to be an important factor involved in the regulation of caspase-independent cell death in neurons and cardiac myocytes *in vitro* during oxidative stress. Excess PARP activation depletes nicotinamide adenine dinucleotide⁺ (NAD⁺) and adenosine triphosphate stores, blocks apoptosis, and results in necrosis.⁴⁰ In addition, peroxynitrite leads to degradation of tetrahydrobiopterin (BH₄), an essential cofactor of eNOS.^{41,42} The classical atherosclerotic risk factors, such as hypertension, smoking, and hyperlipidemia, all act at the endothelial level by increasing oxidative stress, which inactivates NO and upsets the balance between endogenous vasodilators and vasoconstrictors, growth promoters and growth inhibitors, anti-inflammatory and proinflammatory mediators, and other factors important to endothelial function and vascular health.⁴³

The normal endothelium functions in an inhibitory mode, maintaining relaxed vascular tone and inhibiting SMC growth, platelet and leukocyte adhesion and aggregation, and thrombosis. In hypertensive, hypercholesterolemic, and diabetic patients, endothelial dysfunction has been associated with decreased production or decreased activity of NO.⁴⁴ In studies of apolipoprotein E knockout mice, eNOS was ablated and accelerated atherosclerosis was noted.⁴⁵ Endothelial dysfunction is associated with most of the known risk factors for atherosclerosis and cardiovascular disease and may constitute a contributing cause for such disease. This concept has important clinical implications, especially in terms of preventive strategies.

Angiotensin-converting enzyme (ACE) acts both to produce angiotensin II, a potent vasoconstrictor, from angiotensin

I and to degrade bradykinin. Angiotensin II is highly atherogenic, stimulating the synthesis of various growth and chemotactic factors and promoting superoxide anion generation, which degrades NO. In contrast, bradykinin is a vasodilator that exerts its effect via NO. Within the endothelium, excess angiotensin II is not only a vasoconstrictor, but also a promoter of SMC proliferation and migration⁴⁶ and a potent stimulator of inflammatory mediators and growth factors, such as tumor necrosis factor- α (TNF- α), interleukin (IL)-1, IL-6, IL-8, insulinlike growth factor 1 (IGF- β), platelet-derived growth factor (PDGF), transforming growth factor- β (TGF- β), and basic fibroblast growth factor (bFGF).⁴⁶ All these processes can be inhibited or reversed by ACE inhibition therapy because it decreases the level of angiotensin II and inhibits the degradation of bradykinin. ACE inhibitors prevent not only the adverse effects of hypertension, but also the effects of oxidative stress from other mechanisms. Clinical trials have shown that 6 months of ACE inhibition therapy, using quinapril, is associated with a significant improvement in endothelial function in normotensive patients with coronary artery disease.⁴⁷ ACE inhibition at the tissue level appears to be critical to prevent oxidative stress within the endothelium. This is the reason why tissue-avid ACE inhibitors, like quinapril, may have advantages over other drugs in their class. Restoring endothelial function through ACE inhibitors has become an attractive therapeutic target.

REGULATION OF MEDIAL AND INTIMAL THICKENING

Earlier it was observed that, for embryonic vessels to form, primitive endothelial cells must migrate and become aligned and then recruit smooth muscle precursors from the surrounding mesenchyme. Because endothelial cells grow as a monolayer, they can proliferate only when the vascular structure is enlarging in circumference, during vascular elongation (angiogenesis), or when injured endothelium is being replaced. Massive denudation and endothelial loss is not a normal event and probably occurs only during pathologic degeneration of the intima or during surgical instrumentation of the vessel. In any event, endothelial proliferation does not contribute significantly to an increase in wall mass; however, SMC proliferation does.

- 1 Under several circumstances, vessels of adult animals
- 2 respond by becoming thicker. In hypertensive animals and humans, arteries exhibit medial thickening, whereas after endothelial denudation or in the presence of hypercholesterolemia, they develop a thick intima.^{48,49} Exactly how these responses are regulated is not clear, although it is certain that in each instance proliferation of SMCs and accumulation of extracellular matrix are important components. In addition, in hypercholesterolemic subjects, the accumulation of lipid and lipid-filled macrophages contributes to the intimal lesion.⁵⁰

Vessel wall mass is largely determined by the accumulation of SMCs and matrix synthesized by SMCs. Hence, how smooth muscle number is regulated needs to be considered.⁵¹ Under normal circumstances, SMCs proliferate in the vessels of young animals and enter a quiescent state at maturity. For example, SMCs in adult rat carotid artery do not increase in number and turn over at a rate of 0.06% per day.⁵² In animal models of disease, these cells can readily be stimulated to enter the growth cycle by induction of hypertension or direct vascular injury. Observations made in these models provide us with insights into possible mechanisms for initiation and progression of vascular disease in humans.

Although hypertension has its greatest impact on the small "resistance vessels," in fact large arteries are equally affected. In response to increased pressure the wall thickens.^{48,53} Morphometric studies have shown that this increase is largely a

medial process and involves all components of the vessel wall, including the mass of SMCs and matrix. In some forms of hypertension, there is an increase in smooth muscle number, whereas in others there is an increase in the DNA content per cell. Tetraploid and octaploid cells have been detected. In venous grafts transposed from a relatively hypotensive venous environment into the normotensive arterial circulation, there is an increase in wall thickness and a corresponding increase in smooth muscle number.⁵¹ In each instance, the change in pressure affects the mass of cells and associated matrix.

- 3 How a change in pressure might induce SMCs to proliferate, to change their ploidy, or to synthesize matrix is not known. In some circumstances (e.g., severe hypertension, vein grafting), there is a detectable but small amount of endothelial loss.⁵⁴ However, this is not a usual feature in more moderate or chronic forms of hypertension. Leung et al. have suggested that increased tension and stretch have a direct effect on matrix protein synthesis, but not on cell proliferation.⁵⁵ Alternatively, increased wall tension might affect the endothelium, and the endothelium might in turn secrete factors regulating smooth muscle mass.

Of the models of smooth muscle growth in vivo, perhaps the best studied is the balloon injury model first developed by Baumgartner.^{52,56,57} In this model, smooth muscle proliferation is stimulated by the passage of an inflated balloon catheter along an artery. The artery is at once stretched and denuded of its endothelium. Immediately thereafter, platelets begin to adhere to the wall wherever endothelium is missing; they then spread and degranulate. In most situations, endothelial denudation and platelet adherence are followed 1 to 2 days later by the onset of medial smooth muscle proliferation. In the ballooned rat carotid (Fig. 89.4), this can be a most dramatic response with a 3-log increase in the thymidine labeling index (a measure of proliferation). This early proliferation in the media does not lead to an increase in wall thickness; the wall thickens only after SMCs migrate from the media and proliferate in the intima. In normal animals, this process continues for a period of time and subsides spontaneously whether or not endothelium reappears at the luminal surface. The intimal mass is further increased by the accumulation of extracellular matrix synthesized by the SMCs.⁵⁸

A link between smooth muscle proliferation and earlier platelet granule release has been proposed. Among the proteins released are several growth factors including PDGF, TGF- β , and an epidermal growth factor-like protein.⁵⁹ Where these granule proteins go after being released from the platelets is not known. One hypothesis suggests that these factors accumulate in the artery wall and stimulate subsequent smooth muscle growth.⁴⁹ This hypothesis (the reaction to injury hypothesis) was first proposed many decades ago as a general mechanism for atherogenesis and has been refined in view of recent information. Although attractive in theory, it is based on rather slim evidence mainly derived from experiments in thrombocytopenic animals.⁵⁹ Injured arteries in these animals show very little intimal thickening.

The hypothesis that the decrease in intimal thickening in injured arteries of thrombocytopenic animals is attributable to decreased proliferation of SMCs has proven to be incorrect.⁶⁰ In the ballooned rat carotid model, even though intimal thickening is diminished in thrombocytopenic animals, smooth muscle proliferation and early cell cycle gene expression are the same as in controls. The interpretation of these findings is that platelet products play a role in the movement of SMCs from one vascular compartment to the next (media to intima) but do not affect the initiation of proliferation. Whether platelet factors can influence the growth of intimal smooth muscle has yet to be determined.

Although little is known of what starts or stops the intimal thickening process, there are several observations that are interesting and are perhaps important when we consider the current theories of atherosclerosis. The first is that the surface of the injured artery accumulates a single layer of platelets. Fibrin and microthrombi are seen only at the luminal surface when the artery is reinjured after an intimal thickening has formed or in small craters in association with adherent macrophages in hypercholesterolemic animals.^{61–64} Active, fulminant thrombosis is not a usual feature of injured vessels; when it occurs, it must represent a major aberration of vessel function. Second, in models demonstrating early reendothelialization or partial deendothelialization without medial injury, intimal thickening does not develop, although one or two rounds of medial smooth muscle proliferation can occur.⁶⁵

FIGURE 89.4. Elastic arteries injured by the passage of a balloon embolectomy catheter develop substantial intimal thickenings. In this series of histologic cross sections of rat carotid artery before (A) and after ballooning (B–D), the endothelium is stripped away and the inner layer of medial smooth muscle cells is damaged (B). C: By 2 weeks, the intima is thickened by the migration and proliferation of smooth muscle cells derived from the media. The mass of cells does not change significantly after this time; nevertheless, the intima is thicker at 3 months (D) because of matrix synthesis and accumulation. (From Clowes AW, Reidy MA, Clowes MM. Kinetics of cellular proliferation after arterial injury. I. Smooth muscle growth in the absence of endothelium. *Lab Invest* 1983;49:327, with permission.)

FIGURE 89.5. Diagram depicts the complexity of the interactions between vascular wall cells (endothelium and smooth muscle), platelets, and blood-borne leukocytes (monocyte/macrophage and lymphocyte). Each cell is capable of synthesizing and releasing several smooth muscle growth factors and inhibitors.

This result suggests that endothelium might play a role in suppressing smooth muscle growth and migration from the media to the intima. It is known that smooth muscle growth inhibitors can be extracted from the vessel wall, that endothelium can synthesize a heparinlike molecule that inhibits SMC growth in vitro, and that heparin itself can suppress both proliferation and migration of SMC in vitro and in vivo.⁶⁶ Taken together, these findings suggest that the endothelium can inhibit smooth muscle proliferation and that the quiescent state of SMCs in the normal arteries of adult animals might be an actively maintained one rather than one attributable to the lack of growth factors (Fig. 89.5).

REGULATION OF SMOOTH MUSCLE GROWTH

4 Platelets have long been considered the major source of mitogen for proliferating smooth muscle. However, SMCs are able to proliferate in injured and hypertensive arteries when platelets are absent. If platelet factors are not important, what, then, is the stimulus for smooth muscle growth? Three alternatives present themselves: (a) growth factors from vascular wall cells or resident leukocytes; (b) exogenous, neuroendocrine factors; or (c) loss of local inhibitors of smooth muscle proliferation. All three mechanisms might be important. Let us consider the first alternative. It is of some interest that when a rat carotid is denuded of endothelium with a balloon catheter, a substantial fraction of the medial SMCs proliferate (around 20% to 30%), but when denudation is accomplished with a fine nylon wire, there is very little proliferation (around 2% to 4%).⁶⁷ These procedures differ only in regard to the degree to which the media is damaged. Ballooning destroys 20% of the medial smooth muscle, as well as the endothelium, whereas passage of the nylon wire destroys only the endothelium. The observations become more interesting if we note that cultured

cells, when damaged, release growth-promoting activity.^{68,69} The predominant growth-promoting activity is due to fibroblast growth factors (FGFs).^{70,71} These factors have been found in a wide variety of tissues and cell types and are synthesized by endothelium and SMCs. They are distinguished from other polypeptide mitogens by their ability to bind strongly to heparin. Furthermore, both acidic and basic FGFs are potent smooth muscle mitogens in vitro. Finally, FGFs can bind to heparinlike molecules so that released FGFs might readily be “stored” in the heparan sulfate proteoglycan-containing matrix at sites of cell death.⁷² The experiments of Lindner et al. provide strong evidence to support the conclusion that basic FGF is the important growth factor for the first wave of proliferation in balloon-injured rat carotid artery.^{73,74} This mechanism of tissue repair is probably quite relevant for the development of the fibrous cap in advanced atherosclerotic lesions. At these sites, toxic oxidized lipids accumulate, and there is clear evidence of injury and necrosis.⁵⁰ The release of cellular FGF could provide the stimulus for smooth muscle proliferation in the overlying fibrous cap.

Because cell death is not necessarily a prominent feature of growing tissues, there must be other means for controlling smooth muscle proliferation. SMCs not only respond to factors from dead cells, platelets (PDGF, TGF-β, EGF-like molecules), and plasma (thrombin, lipoproteins, IGF-1), but also synthesize and respond to their own secreted factors.⁵¹ Both endothelial and SMCs, as well as macrophages, are potential sources of mitogen. In addition to the FGFs, these cell types synthesize and secrete PDGF, IL-1, TGF-β, and IGF-1.

PDGF in particular has been studied in detail.⁷⁵ The original studies on PDGF stemmed from the observation that serum prepared from whole blood contains substantially more growth-promoting activity than serum prepared from plasma. These findings led to the discovery of PDGF, a basic dimeric protein with a molecular weight of approximately 30,000. It is transported in the blood in the α granule of the platelet and is released along with other α-granule proteins. PDGF is by itself

extremely potent and is active as a smooth muscle mitogen in trace amounts (nanogram per milliliter). It also exhibits a range of other activities on smooth muscle and other types of cells (stimulates smooth muscle migration, contraction, and matrix synthesis), although it is not a mitogen for endothelium. When placed in a wound chamber *in vivo*, it induces a granulation tissue response.⁷⁶

An important development in the field of growth factor research in the last decade was the demonstration that the structure of the gene for PDGF is nearly identical to that of the oncogene *v-sis*, a gene associated with cellular transformation by the simian sarcoma virus.^{77,78} This discovery, coupled with the finding that a variety of cells including normal cells synthesize and secrete active PDGF, raises the possibility that normal wound healing and malignant, unscheduled growth of tumor cells might have striking similarities with subtle differences in gene regulation. It also led to a search for growth factors in vascular wall cells. We now have solid evidence that endothelium, SMCs, and leukocytes, including macrophages, can express the PDGF gene (*c-sis* or PDGF B chain) *in vitro* and *in vivo*.⁷⁵ PDGF research is complicated by the observation that PDGF is not a single molecule, but is either a heterodimer or homodimer of two isoforms, PDGF A and PDGF B. The cellular receptors are also dimers of two isoforms, α and β , such that PDGF B binds to both α and β , but PDGF A binds only to the α form of the receptor. The implications of this complexity of growth factor and receptor expression have yet to be understood. At present, we know that human platelets transport mainly PDGF AB, whereas cultured SMC from human plaques, baboon graft intima, and injury-induced rat intimal thickening express mainly PDGF A-chain mRNA. This observation is probably not an artifact of cell culture because the primary lesions from which the cells are derived contain relatively large amounts of A-chain mRNA. Macrophages in atherosclerotic lesions express PDGF B protein. What role PDGF plays in wall function remains to be determined. It is not clear how the expression of the protein is regulated, nor is it clear whether regulation also occurs at the level of receptor expression. These findings suggest the intriguing possibility that the vascular wall cells, as well as the platelets, are a source of growth factors in the artery wall, and through the endogenous production of growth factors thus might be able to regulate their own growth (autocrine control) or their neighbor's growth (paracrine control). Alternatively, PDGF might control some other function than proliferation. At least after injury and in atherosclerotic mouse arteries, PDGF may act as a chemoattractant and regulate the movement of SMCs from the media into the intima or from the wall into the overlying thrombus.^{79,80} In SMC migration, PDGF uses a different signaling pathway than that used for proliferation.⁸¹

Another alternative for regulation, in addition to factors from the blood and the cells themselves, is neuroendocrine control of smooth muscle growth.^{82,83} Several neurotransmitters affect smooth muscle hypertrophy and proliferation (serotonin, neurokinin A, substance K, substance P). Furthermore, sympathectomy or inhibitors of sympathetic nerve function inhibit the increase in DNA in the media of developing arteries and arteries subjected to hypertension.^{84,85} In injury models, prazosin (an α_1 antagonist) and cilazapril (an ACE inhibitor) both inhibit intimal thickening.^{86,87} These recent observations provide some support for the possibility that neuroendocrine factors also influence intimal smooth muscle proliferation.

Although smooth muscle mass may be determined in large measure by the presence or absence of growth factors (i.e., positive effectors of growth), smooth muscle mass might also be influenced by endogenous inhibitors. Growth might be viewed as release from quiescence. Earlier, it was pointed out that endothelial regeneration in injured arteries is associated with cessation of underlying intimal smooth muscle growth. On the other hand, in healing vascular grafts, intimal SMCs proliferate only underneath the newly formed endothelial surface.⁸⁸ These

observations are in parallel with studies of endothelial and SMCs in culture demonstrating that vascular wall cells can synthesize and secrete both inhibitors and promoters of smooth muscle growth.¹⁵ The growth-promoting factors have already been described. Both cell types synthesize heparan sulfate, which, when released from the larger proteoglycan, can inhibit the growth of cultured SMCs.^{89,90} Both cell types synthesize and secrete a TGF- β precursor,⁹⁰ and TGF- β can be found in the arterial wall after injury.⁹¹ The precursor molecule can then be activated. In general, TGF- β acts as an inhibitor, although at times it can promote smooth muscle growth. Antibody to TGF- β administered to rats suppresses injury-induced intimal thickening.⁹² There are other growth inhibitors *in vivo* that might be released by leukocytes present in the vascular wall. Although this mechanism is not important for the regulation of mass in normal artery, it is probably very important in diseased vessels. In atherosclerotic plaques there are large numbers of macrophages and lymphocytes. Hansson et al.⁹³ have shown that resident T cells secrete interferon- γ and induce the expression of class II major histocompatibility antigens. Interferon- γ also inhibits smooth muscle growth in culture, and in the injured rat carotid, there is a significant population of I_a -positive, growth-inhibited intimal SMCs.⁹⁴ Although SMCs make up the bulk of the intimal thickening, 1% or less of the intimal cells are T cells. Because I_a expression is absolutely dependent on the presence of interferon- γ , these observations strongly support the view that interferon- γ is an endogenous regulator of intimal smooth muscle growth. A recent study of the effects of interferon- γ refutes this conclusion and suggests that it may at times promote SMC growth.⁹⁵ Finally, growth of vascular wall cells might be regulated not only by secreted soluble factors, but also by direct cell-cell contact. This inhibitory mechanism is very important for endothelium and perhaps less so for SMCs.

These growth factors exert their effects via specific receptors located in the cell membrane. The majority of growth factor receptors belong to a family of peptide receptors called receptor tyrosine kinases (RTKs). A growth factor's function can be endocrine, paracrine, or autocrine in nature. A growth factor's function is said to be endocrine when it is released in the circulation and exerts its function after attaching to receptors located on cells in a distant organ. A growth factor acts in a paracrine manner when it affects cells located in the vicinity of the cell that secreted it. A growth factor can also cause its effect on the same cell that secretes it in an autocrine manner. In each of these situations, the growth factor interacts with its own specific receptors located on distant cells, on adjacent cells, or on the same cells that secreted it. The paracrine and autocrine functions are important in case of arterial injury. When endothelial cells and SMCs are injured, they secrete growth factors, such as PDGF, that bind to receptors on the same or adjacent cells, causing SMC proliferation and migration to form intimal hyperplasia.⁴⁹

Once the growth factor binds to the extracellular domain of its receptor, the kinase function becomes activated and phosphorylates specific cytoplasmic substrates to activate pathways required for the function of the growth factor. Various growth factor receptors use different specific substrates for their actions and the same growth factor may use a different substrate depending on the ultimate action required, whether it is cell division, motion, or differentiation. Therefore, the most important events in signal transduction take place in the cytoplasm of the cell.⁹⁶ Triggered by growth factor attachment, the intracellular domains interact on a molecular level. Then, intracellular protein molecules belonging to various protein families bind to specific sites along the intracellular cytoplasmic domain of the phosphorylated receptor. These proteins carry specific recognition sites that allow a certain family of proteins to bind to a specific area of the intracellular domain. By doing so, various cellular signaling pathways are activated. Each pathway controls a specific function of the

growth factor. The recognition sites found on the cellular proteins are called src homology-2 (SH-2) or src homology-3 (SH-3) domains. In addition, the SH-2 and SH-3 phosphorylated sites of the protein serve to bind them to other cellular proteins that belong to the signaling cascade. Proteins that are involved in these pathways include guanosine triphosphatase-activating protein (GAP), phospholipase C (PLC), and phosphatidylinositol-3-kinase (PI-3-K)-binding protein. These cascades of phosphorylation and specific protein binding eventually lead to a specific function of the growth factor; the function may be one of differentiation, proliferation, cell shape changes, or motility.⁹⁷

The signaling pathways or cascades rely on the proteins' phosphorylation for the signal to be transmitted to the nucleus and cause gene activation. One of these pathways is called the Ras pathway. Once the growth factor attaches to its receptor, the receptor phosphorylates itself. Ras, a protein that attaches to the cytoplasmic aspect of the cellular membrane, undergoes phosphorylation and activates Raf-1 protein, which indirectly phosphorylates mitogen-activated protein kinase (MAPK). MAPK phosphorylates transcription factors inside the nucleus (e.g., Myc, jun) that stimulate gene activity.⁹⁷ The Jak-STAT pathway is another important signaling pathway that was recently described.^{98,99} Signal transducers and activators of transcription (STATs) are families of proteins that have been found to be phosphorylated by Jaks, kinase enzymes activated in response to growth factor interaction with its receptor. The two pathways, Ras and Jak-STAT, may intersect on the way to the nucleus to cause gene activation. It is believed that MAPK from the Ras pathway enhances STAT activity by causing additional phosphorylation.¹⁰⁰

Direct cell-to-cell communication and the presence of gap junctions have been demonstrated in monolayers of endothelium¹⁰¹ and in mixed cell populations between endothelium and SMCs.¹⁰² The significance of these direct links has not been defined, although a recent study has demonstrated that cultured pericytes or SMCs can inhibit endothelial growth when the cells are in contact with one another. In vivo capillary endothelial cells appear to grow when pericytes are absent and to stop growing when pericytes reappear. Endothelial cells can also regulate the growth of one another. Plasma membrane preparations from confluent large-vessel endothelium actively inhibit growing endothelial cells.¹⁰³ The intercellular links might help to regulate endothelial proliferation and endothelial-mediated vascular relaxation in collateral vessels by propagating signals from one cell to the next upstream from a large vessel occlusion. Direct cell-cell communication would also provide a mechanism for a local response in a vessel without the need for the release and wide dissemination of potent vasoactive or growth regulatory substances.

In summary, the size of a vessel wall is dependent on the mass of cells and matrix. Because SMCs and associated matrix proteins make up the bulk of the tissue, an understanding of the regulation of smooth muscle growth during development and in diseased states is extremely important. Smooth muscle number and distribution are affected by growth factors from the blood (particularly from platelets and leukocytes), growth factors and inhibitors from the vascular wall cells themselves, and neuroendocrine factors particularly from sympathetic innervation of the vessel wall. Smooth muscle quiescence in the normal adult artery might be maintained by heparinlike inhibitors synthesized by vascular wall cells or the absence of growth factor. Growth initiation might be due to a shift in the balance of these negative and positive stimuli (Fig. 89.5). For example, any condition causing injury of vascular wall cells or inducing the influx of macrophages would be expected to set up a favorable environment for smooth muscle growth. Hypercholesterolemia, a significant risk factor for atherosclerosis, is associated with macrophage migration and the accumulation of toxic oxidized LDL in susceptible large arteries. Release of endogenous FGF from dying foam cells as well as release of

other growth factors (possibly PDGF) from stimulated endothelium, smooth muscle, and macrophages would increase the local concentration of growth-promoting activity. SMCs would be expected to respond by proliferating and migrating into the intima; if collections of these cells were already present in the intima as a consequence of fetal development, they might be even more responsive. These factors might also regulate the traffic of other leukocytes (macrophages, T cells) in and out of the wall, and these activated cells would in turn amplify or retard the initial smooth muscle response by the production of growth factors or inhibitors. The extent and complexity of these interactions between the cells of the wall and the blood have yet to be unraveled.

REGULATION OF THE ANTICOAGULATED STATE

Blood does not clot in normal arteries even when flow is stopped for prolonged periods. On the other hand, endothelial injury or loss provokes a dramatic thrombotic response. These observations define the importance of the endothelial layer in the maintenance of the anticoagulated state.^{104,105} Studies performed primarily on cultured cells have demonstrated that endothelial cells possess an array of anticoagulant and antithrombotic functions, and it is certain that many of these are of importance in vivo. Endothelial cells also have several procoagulant functions, and the balance between procoagulant and anticoagulant functions is regulated by signals from the blood, as well as from neighboring cells.

On the anticoagulant side of the balance, the endothelium synthesizes a membrane-associated heparan sulfate that, like heparin, increases the affinity of antithrombin III for thrombin.¹⁰⁶ Because this interaction requires the binding of heparan sulfate to antithrombin III, the complex must be active at the level of the endothelial surface. Heparin-antithrombin III then rapidly inactivates circulating thrombin and other activated serine proteases in the clotting cascade, including factors VII, IX, and X. Thus, endothelial-derived heparin sulfate can act to impede two aspects of the injury response: the activation of the clotting cascade and the stimulation of smooth muscle proliferation, which we referred to earlier. In addition, endothelial cells can inhibit clotting by means of the protein C pathway.¹⁰⁰ Endothelium synthesizes and secretes a protein called thrombomodulin, which in turn is bound to a surface receptor. The receptor-thrombomodulin complex binds thrombin and in so doing inactivates the proteolytic activity for fibrinogen. The thrombomodulin-thrombin complex activates protein C, and the activated protein C binds to protein S on the endothelial surface. The protein C-protein S complex then can inactivate factor Va, thereby inhibiting the clotting cascade. That this pathway is important is amply demonstrated in homozygous protein C-deficient patients who develop spontaneous thrombosis. Finally, endothelial cells can inhibit platelet adhesion and aggregation through the synthesis of prostaglandin I₂ (PGI₂) and can degrade formed fibrin by activating plasminogen to plasmin.

On the procoagulant side, endothelial cells synthesize and secrete tissue factor, platelet-activating factor, a plasminogen activator inhibitor, and von Willebrand factor, and they express a number of receptors for factors of the clotting cascade.¹⁰⁴ When the cells are exposed to a variety of inflammatory mediators derived from the blood or from resident macrophages (e.g., endotoxin, IL-1, TNF), endothelial cells respond by changing the balance of anticoagulant-procoagulant activities to favor coagulation. As well, the cells synthesize and express IL-1, which potentially could affect the underlying SMCs.¹⁰⁷ At present, these conclusions are largely based on in vitro experiments; although they have relevance mainly for the microvasculature, they also may prove to be important for large vessels in view of the recent evidence that not only macrophages but

also different populations of lymphocytes are present in the atherosclerotic plaque. Furthermore, the ability of the vascular wall cells to maintain the anticoagulant state at the luminal surface must have a direct bearing on the thrombotic complications associated with end-stage atherosclerosis.

LESIONS OF ATHEROSCLEROSIS

Atherosclerosis is a disease of the intima characterized by the accumulation of SMCs and lipid.^{107,108} The earliest lesion appears to be a local accumulation of lipid in the vessel wall located either in the extracellular matrix or inside “foam cells” (lipid-filled SMCs or macrophages). The relationship between the so-called fatty streak (Fig. 89.6) made up of foam cells and the pathologic process of atherosclerosis, the fibrous plaque, and the complicated lesion has been the subject of some debate.¹⁰⁹ Fatty streaks are found even in young children. Although atherosclerosis has a predilection for certain countries, the extent of fatty streaks of the aorta and coronary arteries in young people is about the same in countries that have low mortality rates from heart attack as in countries with high rates. The lipid streaks have been found to be just as common in females as in males, although atherosclerosis is more prevalent in males. Finally, even though the lipid streaks are distributed throughout the aorta, end-stage disease is mostly confined to the abdominal segment. Hence, if the fatty streak is the precursor of the more advanced lesion, then there must either be a selection process or the whole concept must be wrong. The issue remains unresolved.

An alternative precursor for the atherosclerotic plaque is the intimal cell mass.^{110,111} These focal accumulations of SMCs are frequently found in the vessels of children in locations that later develop fibrous plaques. In fat-fed swine, the intimal cell masses enlarge and become atherosclerotic.¹¹² Although the concept of the intimal cell masses as the initial lesion is attractive, there are several problems with it. First, this initial lesion is present in people throughout the world regardless of eventual risk for atherosclerosis. Second, as a general rule there is a gradual thickening of the intima throughout the arterial tree as part of the aging process; this has little to do with atherosclerosis. Finally, it has been difficult to find animal models of atherosclerotic change in intimal masses, whereas the formation of fibrofatty lesions from fatty streaks has been rather easily modeled by cholesterol feeding in a number of species. For these reasons, support for the intimal cell mass as the initial lesion has not achieved wide acceptance.

5 Whatever the initial lesion might be in atherosclerosis, it is widely agreed that the lesions characteristic of late atherosclerosis

are the fibrous and the complicated plaques. The fibrous plaque is characterized by a thick fibrous luminal cap containing SMCs and leukocytes overlying a central core of necrotic debris and lipid (the “atheroma”). Animal studies have suggested that there might be either denudation or nondenuding injury of the endothelium at the surface.⁶³ The functional state of the endothelial cells and SMCs and leukocytes in these lesions is not known. Macrophages, by becoming foamy, clearly play a role in the metabolism of lipid, and activated macrophages also secrete a range of factors that modulate the metabolic and growth state of the vascular wall cells. Macrophages also proliferate locally in the lesions.^{113,114} In addition, other leukocytes, particularly T lymphocytes, are present; because some adjacent SMCs express the class II antigen human leukocyte antigen (HLA)-DR, they must be exposed to interferon- γ presumably derived from the neighboring T cells.¹¹⁵ In addition to inducing the expression of HLA-DR, interferon- γ inhibits smooth muscle proliferation. Hence, in the advanced atherosclerotic lesion these leukocytes might play a critical role in regulating smooth muscle proliferation and accumulation.^{116,117}

6
7
8 The complicated lesion of atherosclerosis is a fibrous plaque with the additional features of ulceration, luminal thrombosis, calcification, and wall hemorrhage (Fig. 89.6). It is the source of the thromboembolic activities associated with symptomatic disease. Why a fibrous lesion evolves into a complicated plaque is not understood. This process might be accelerated by such risk factors as hypertension, whereas atherogenesis might be affected more by hypercholesterolemia and cigarette smoking. More importantly, the advent of the inflammatory cells and the release of potent mediators of inflammation must play a role in the development of the complicated lesion. Earlier it was pointed out that growth factors for smooth muscle not only were liberated from platelets, but also were synthesized and secreted by macrophages and the vascular wall cells themselves. In addition, potent cytokines, such as IL-1, TNF, and interferon- γ , alter the growth state and metabolism of the vascular wall cells. In particular, the balance of anticoagulation-coagulation at the surface of the endothelium might be shifted away from anticoagulation and toward coagulation. In the plaque, large amounts of tissue factor and plasminogen activator-1 (PAI-1) are present.¹¹⁸⁻¹²⁰ These changes, in addition to frank endothelial desquamation in response to injurious agents, including oxidized LDL, homocystinemia, and tobacco products, could promote thrombosis in the vessel, an event that is decidedly unusual. Small accretions of thrombus with subsequent fibrotic remodeling together with hemorrhage from new blood vessels in the ischemic central region of the plaque could account for the relatively rapid increase in

plaque size and luminal narrowing that has been observed in some arterial beds.

THEORIES OF ATHEROSCLEROSIS

Some of the information on vascular wall structure and function might be relevant to general theories of atherosclerosis. From the foregoing, it should be evident that an artery is not just an inert nonthrombogenic conduit for blood; rather, it is an organ whose structure and function are very carefully modulated by interactions between vascular wall cells themselves and between vascular wall cells and the blood. Bearing this in mind, we can reexamine the prevailing theories of atherosclerosis.

Over the last century, a number of theories have been advanced to explain how atherosclerosis evolves. In reality, these theories attempt to account for one or more aspects of the disease and are therefore not mutually exclusive. Much of the controversy over these theories has to do with individual opinion concerning which of the aspects of atherosclerosis is most important.

Lipid Insudation Hypothesis

Perhaps the oldest hypothesis, termed the “lipid insudation” hypothesis, states that the lipid in the atherosclerotic lesion is derived from lipoproteins in the blood^{50,121}; it thereby links the risk factor hypercholesterolemia directly to the development of the plaque foam cell, the atheroma, and eventually the complicated lesion. There is good evidence now that the lipid in the plaque comes from the blood; there is also substantial evidence correlating the severity of hypercholesterolemia (particularly elevated LDL cholesterol) with the severity of atherosclerosis both in human and in animal models. When animals are made hyperlipidemic, the initial change is a migration of macrophages through the endothelium into the subintima and media. These cells then engorge the lipids carried into the wall by lipoproteins to form foam cells. These foam cells presumably secrete chemoattractants, growth factors, and cytokines, which trigger off complex events that lead to the formation of an atherosclerotic plaque.¹²² The most important study to demonstrate that blood cholesterol level is a risk factor for coronary artery disease and hence atherosclerosis is the Framingham study. A large group of healthy men and women were studied and it was found that the risk for developing clinically evident coronary artery disease was related to cholesterol levels.¹²³ Although a high level of LDL cholesterol is an important risk factor for atherosclerosis, epidemiologic studies have shown that levels of apolipoprotein B, the primary protein constituent of LDL, very low-density lipoprotein (VLDL), and chylomicrons, correlate more accurately with the risk of atherosclerosis. Particles resembling VLDL and intermediate LDL have been identified within the atherosclerotic plaque.¹²⁴ High-density lipoproteins (HDLs) oppose the deposition of cholesterol by transporting cholesterol to the liver. Thus, low levels of HDL correlate with an increased risk of atherosclerosis and high levels of HDL are protective. The lipid insudation theory states that the lipid in the atherosclerotic lesion is derived from the lipoproteins in the blood.^{50,125} The earliest lesions induced by elevated plasma cholesterol levels are the fatty streaks, which have an impressive accumulation of lipids in them. For a considerable period of time it was thought that the lipid-containing foam cells were derived from SMCs, but there is considerable evidence now that most of these cells originate from circulating monocytes/macrophages and only a fraction represent cholesterol-laden SMCs. Although not all fatty streaks become fibrous plaques, results from the Pathological Determinants of Atherosclerosis in Youth program have shown that atherosclerosis commences as a fatty streak, which progresses to the complicated lesion, namely, the fibrous plaque.¹²⁶

It is still unclear as to how the monocytes penetrate the endothelium to reach the subendothelial space. The endothelial injury hypothesis postulates that there is endothelial denudation that allows this penetration, but a number of experimental studies have failed to show any damage to the endothelium over the fatty streaks. Once in the subendothelial space of the intima, the monocytes take up lipoprotein cholesterol to become foam cells. Denudation of endothelial cells probably occurs later in the development of the lesion, exposing the underlying foam cells. Brown et al.,¹²⁷ however, showed that even the highest concentration of LDL could not induce the accumulation of cholesterol in monocytes/macrophages or in SMCs, the precursors of arterial foam cells. Thus, it is not the circulating LDL that causes lipid accumulation in the monocytes/macrophages, but the oxidized LDL that is taken up avidly by the macrophages. Oxidized LDL is more atherogenic than native LDL, and in animal models antioxidant compounds can slow the rate of atherosclerotic lesion progression by 50% or more.¹²⁸ In addition, two antioxidant enzymes are associated with HDL, paraoxonase and platelet-activating factor acetylhydrolase. These factors are believed to degrade deleterious oxidized phospholipids associated with LDL.¹²⁹ There is a good deal of epidemiologic evidence correlating high intake of antioxidant vitamins with decreased risk of coronary artery disease in humans.¹³⁰ However, the results of randomized clinical trials have not demonstrated a decrease in progression of atherosclerosis. These trials have failed to demonstrate a consistent significant effect of single or multivitamin regimens on the incidence of death from coronary vascular disease.^{131,132}

Regarding the role of genetic background in the development and progression of atherosclerosis, Dansky et al.¹³³ have demonstrated that expression of the human apo A-I transgene on the apo E-deficient background increases HDL cholesterol and greatly diminishes fatty streak lesion formation. They also demonstrated that increases in apo A-I and HDL cholesterol inhibit foam cell formation in apo E-deficient/human apo A-I transgenic mice at a stage following lipid deposition, endothelial activation, and monocyte adherence, without increases in HDL-associated paraoxonase.

The role of “statins” in delaying the progression of the atherosclerotic lesion has been investigated. Several studies, such as the Coronary Primary Prevention trial and the Helsinki Heart Study, have shown a relation between reduction in the lipoprotein profile and a reduction in the cardiac events. In the first study, a 20% reduction in LDL cholesterol yielded a more than 30% reduction in coronary events, and in the second study, gemfibrozil reduced LDL cholesterol by 8% and triglycerides by more than 35%, while causing a 15% increase in HDL and reduced coronary events by 34%.^{134,135}

The discovery of the statin (e.g., simvastatin, lovastatin) group of drugs was a major advance in the pharmacologic management of hypercholesterolemia. The statins are analogues of 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) reductase; therefore, they block its action and inhibit the synthesis of cholesterol. Statins are highly effective agents for the primary and secondary prevention of coronary artery disease. Although lowering of cholesterol, especially LDL cholesterol, appears to be the most important mechanism for the beneficial effects of statins, other effects including improvement in endothelial function may also play an important role. The inhibition of cholesterol synthesis increases hepatic expression of the LDL receptor, leading to increased clearance of circulating LDL. Several studies have shown that lipid-lowering statin therapy leads to a reduction in cardiovascular events and mortality from cardiac events.¹²⁹ These studies also showed a reduction in the incidence of stroke, which has a relatively weak association with cholesterol levels. In the preliminary results of the Heart Protection Study, there is evidence that long-term statin use reduces the incidence in cardiovascular events in patients with coronary artery disease, carotid artery disease, peripheral vascular disease, or diabetes regardless of baseline LDL

cholesterol level.^{136,137} Simvastatin and lovastatin have been shown to reduce vascular injury from experimental stroke in a rodent model, independent of lipid changes.¹³⁸ Decreasing inflammation by lowering LDL cholesterol, and thus oxidized LDL cholesterol, is one theory on the mechanism of action of statins. Studies using C-reactive protein (CRP) as a marker of inflammation have shown a decrease in CRP along with a decrease in LDL in patients on statin therapy. However, other studies have not shown the same correlation and this has fostered a lipid-independent theory. Further studies are being conducted to elucidate the mechanism of the statins' effect.¹³⁹

The Encrustation Hypothesis

Like the lipid insudation hypothesis, the encrustation hypothesis focuses on one aspect of the disease.¹⁴⁰ This hypothesis proposes that plaque initiation and progression are the consequence of repeated cycles of thrombosis and remodeling. However, autopsy studies of vessels of children and experiments with cholesterol-fed animals have shown that thrombosis is not the initial event in atherogenesis; in fact, thrombosis appears to be a feature of advanced disease. Hence, this hypothesis is applicable only to the problem of plaque progression. Furthermore, it does not explain how lipid and SMCs accumulate in the lesion.

The Reaction to Injury Hypothesis

This hypothesis attempts to explain how smooth muscle growth is regulated in atherogenesis.⁴⁹ As originally proposed, it stated that the initial event is some form of injury to the endothelium. In regions denuded of endothelium, platelets adhere and release growth factors; these growth factors accumulate in the wall and stimulate medial smooth muscle proliferation and migration into the intima. As discussed previously, this theory is based on the observation that platelets carry potent smooth muscle mitogens in their granules and that the injury-induced arterial lesion closely resembles the fibrous cap found in the atherosclerotic plaque. A modified version of this theory suggests that injuries to the endothelium, which do not produce denudation, might also cause smooth muscle growth by stimulating damaged endothelium to synthesize and release growth factors. Alternatively, monocytes might be attracted to the zone of injury; the monocyte/macrophage might then be activated and start to elaborate growth-promoting activity. The reaction to injury hypothesis suggests a possible mechanism for the accumulation of connective tissue cells and matrix; it fails to provide an explanation for the lipid accumulation or the monoclonal nature of the advanced atherosclerotic plaque.

The Monoclonal Hypothesis

This hypothesis focuses attention on smooth muscle accumulation in the lesion.¹⁴¹ It states that the cells of any particular plaque are likely to arise as a clone from a single progenitor SMC. This hypothesis is based on the observation that individual plaques of human females heterozygote for the X-linked marker glucose-6-phosphate dehydrogenase (G-6-PD) frequently exhibit one, but not both, of the G-6-PD isotypes. At a certain moment in time, single cells might be stimulated to enter the growth cycle and undergo several rounds of division leading to the formation of a monoclonal lesion. The mechanism of cell activation leading to such lesions is not evident as yet; the only other known monoclonal cell masses in humans are neoplasias (e.g., leiomyomas). This would tend to suggest carcinogens or possibly viruses as possible etiologic agents and thereby might explain the link between cigarette smoking and atherosclerosis. An alternative to carcinogenesis as an expla-

nation for monoclonality is the possibility of activation of a susceptible population of stem cells.^{142,143} SMCs might have limited replicative capacity, and there might be only a small population of stem cells in the wall capable of responding to growth factors. Whatever the mechanism of activation might be, any theory attempting to provide a mechanism for the accumulation of SMCs in atherosclerotic plaques must take into account this observation of monoclonality.

The Intimal Cell Mass Hypothesis

This hypothesis was mentioned earlier and states that the accumulations of intimal SMCs are one of the two possible initial lesions in atherosclerosis.^{110,111} These small accumulations of SMCs are found in children at sites where atherosclerosis later develops. How they happen to get there is unclear, nor is it evident what makes them susceptible to atherogenic stimuli. It could be that these cells are primordial rests and really are a form of stem cell capable of responding to external mitogenic stimuli. Because the intimal cell masses are found in the vessels of children throughout the world regardless of the prevalence of atherosclerosis, it is likely that the atherosclerotic change is largely determined by extrinsic risk factors, such as hypercholesterolemia.

The Infection Hypothesis

Although the role of infection in the development of atherosclerosis has been debated for many years, only recently this role has been emphasized due to a panel convened by the National Heart, Lung, and Blood Institute (NHLBI).¹⁴⁴ The expert panel examined the evidence linking infections to the development of the atherosclerotic process, in particular the role of cytomegalovirus (CMV) and *Chlamydia pneumoniae*. The panel reported on the seroepidemiologic evidence and the reports localizing those infectious agents to the human plaque. In addition, they examined animal studies aiming to show cause and effect among CMV, *C. pneumoniae*, and the development of atherosclerotic lesions in animal models.

CMV belongs to the herpesvirus family, which also includes the Epstein-Barr virus. Approximately 15% of adolescents, 50% of adults by age 35, and 70% of patients older than 75 years have evidence of past infection with this virus.¹⁴⁵ Melnick et al.¹⁴⁶ found significantly higher titers of CMV antibodies in patients undergoing coronary artery bypass surgery (70%) compared to matched controls (43%). Cardiac transplant recipients with CMV exposure, as evidenced by increased serum CMV immunoglobulin G (IgG) antibodies, are more likely to develop posttransplantation atherosclerosis than patients without exposure to CMV.¹⁴⁷ CMV infection has been associated with restenosis following coronary angioplasty.¹⁴¹ In addition, CMV has been implicated in the development of carotid atherosclerosis. CMV antigens have been isolated from carotid plaque, and increased levels of CMV antibody titers are associated with carotid intimal-medial thickening.¹⁴⁸ Although it has been difficult to culture viral particles from atherosclerotic lesions, this by itself does not constitute strong evidence against the role of CMV infection in atherosclerosis because it is possible that the virus triggers the infection without persisting in the tissue.^{145,146,148} Because of the ubiquitous nature of CMV, it is difficult to ascertain whether it is a pathogen in atherosclerosis.¹⁴⁹

Three species of *Chlamydia*, *Chlamydia trachomatis*, *Chlamydia psittaci*, and *C. pneumoniae*, which are gram-negative bacteria, are known to cause human disease. *C. pneumoniae* cause upper respiratory infections and 10% of all cases of pneumonia. The prevalence of antibodies to *C. pneumoniae* is around 50% in adults.¹⁴⁹ *C. pneumoniae* organisms have been isolated from atherosclerotic plaque from both carotid and coronary arteries.^{150,151} In a rabbit model, infection

with *C. pneumoniae* has been shown to accelerate the formation of the atherosclerotic lesion. In addition, treatment with azithromycin prevented the formation of the lesion.¹⁵² To gain insight into the mechanism by which *C. pneumoniae* infection affects the process of atherogenesis, Kol's group studied atherosclerotic plaques for the presence of chlamydial heat shock protein 60 (HSP60).^{153,154} Studying plaques from human carotid atherosclerotic arteries, these investigators found that chlamydial and human HSP60 colocalize within macrophages located in the atherosclerotic lesions. They have also shown that both chlamydial and human HSP60 induced the production of TNF- α and matrix metalloproteinase (MMP) by macrophages. They concluded that, by inducing the production of such factors by macrophages, chlamydial HSP60 may represent the mechanism by which infection with *C. pneumoniae* promotes atherosclerosis.¹⁵³ In addition, the same investigators have shown that chlamydial and human HSP60 activate human endothelial cells, SMCs, and macrophages to secrete factors (e.g., E-selectin, intercellular adhesion molecule-1 [ICAM-1], and vascular cell adhesion molecule-1 [VCAM-1]) important to the pathophysiology of atherosclerosis.¹⁵⁴

In addition to CMV and *Chlamydia*, *Helicobacter pylori* and herpes simplex virus are also being investigated as possible agents in atherosclerosis.¹⁵⁵ More work needs to be done to definitively establish the relationship between these and other agents and atherosclerosis. Establishing the role of infectious agents in the development of atherosclerosis is very important because it suggests that anti-infectious agents, such as known antibiotics, may play a role in preventing or slowing the atherosclerotic process.

Inflammatory and Immune Hypothesis

Mediators of inflammation, such as cytokines and growth factors, have been found in the atherosclerotic plaques. These mediators are involved in the synthesis and degradation of collagen by vascular SMCs. Such mediators include TGF- α and interferon- γ .¹⁵⁶ IL-2 receptors are markers suggesting the activation of T lymphocytes, and interferon- γ is produced and secreted by activated T lymphocytes.¹⁵⁷

The involvement of macrophages and T lymphocytes in atherogenesis also suggests both an immune and an inflammatory response. The lymphocytes found in atherosclerotic lesions are polyclonal, indicating that these cells do not develop in response to a single antigen. Several different subclasses of T lymphocytes have been identified in atherosclerotic plaque, including both CD4 (helper-inducer cells) and CD8 (cytotoxic T cells).¹⁵⁸ In addition, accelerated coronary artery atherosclerosis is a unique variant of atherosclerosis that develops and progresses rapidly in transplanted hearts, suggesting an immunologic etiology. The lesions seen in transplanted hearts involve the entire coronary tree, and these lesions contain all the cellular elements characteristic of atherosclerosis; in addition, they have increased numbers of T lymphocytes and macrophages compared to the typical atherosclerotic lesion.¹⁵⁹ Mouse transplant models, using heterotopic heart transplants and arterial interposition grafts, produced arterial lesions that resembled transplant arteriosclerosis.^{160,161}

Activation of the complement system is an important step in the immune process causing immune complexes to deposit in the arterial wall or precipitating the binding of specific antibodies to antigens found in vascular tissues. Cholesterol particles are potent activators of the complement system.¹⁶² This activation of the complement system results in the production of proinflammatory molecules and the terminal membrane attack complex (MAC), which has been known to stimulate the production of cytokines, such as TNF- β and IL-8, and growth factors, such as basic FGF and PDGF by vascular smooth muscle cells (VSMCs) and endothelial cells.¹⁶² MAC has been identified in atherosclerotic lesions, particularly fibrous plaque.¹⁶³

FIGURE 89.7. Plaque cap rupture exposing the lipid core of the atheroma and leading to thrombus formation. (Courtesy of Dr. Maria de Lourdes Higuchi, Department of Pathology, University of São Paulo, Brazil.)

Most complications related to atherosclerotic lesions may be due to plaque disruption or rupture. Plaque disruption exposes the circulating blood to its lipid core with subsequent formation of thrombus (Fig. 89.7), leading to acute arterial occlusion.^{164,165} Plaque stability is very important in preventing plaque rupture. This stability is provided by the integrity of the extracellular matrix within the plaque. Plaque instability is related to the degree of inflammation because inflammatory cells produce cytokines that decrease the production of collagen or increase its degradation.¹⁶⁶ Therefore, the balance between the production of MMPs, which degrade collagen, and that of tissue inhibitors of metalloproteinases (TIMPs) regulates plaque stability.¹⁶⁷ The expression of both MMPs and TIMPs can be demonstrated in atheromas. TIMPs have been found in macrophages present within plaques.¹⁶⁷ Inflammatory cytokines, such as IL-1 and TNF, can induce the expression of MMPs by macrophages.¹⁶⁸ In addition, interferon- γ produced by T lymphocytes decreases collagen production, again leading to weakening of plaque extracellular matrix and rupture.¹⁶⁹ The foam cells express tissue factor on their surface and activate factor VII, which leads to thrombin formation and platelet aggregation, with subsequent conversion of fibrinogen to fibrin leading to thrombosis.¹⁷⁰ Interestingly, lipid-lowering strategies led to a decrease in plaque content of macrophages and a decrease in expression of MMP1, increasing collagen production and retention, which improve plaque stability.^{168,171}

Arterial endothelial cells possess a single cilium able to detect the mechanical forces of blood flow that distinguish disturbed from laminar flow. The type of flow then dictates endothelial cell phenotype. Cells at plaque-susceptible sites have a proinflammatory phenotype. This phenotype is both permissive and causative of plaque development. The proinflammatory endothelial phenotype is permissive in that it allows the expression of proinflammatory receptors, such as Toll-like receptors (TLRs). The phenotype is also causative in that it permits the expression of cell surface adhesion molecules, like VCAM-1, which foster leukocyte accumulation in the intima. No specific disease risk has been identified that would promote a proinflammatory phenotype at only arterial bifurcations and the lesser curve of the aortic arch; however, TLRs expressed by the endothelial cells at these locations may provide an insight.¹⁷²

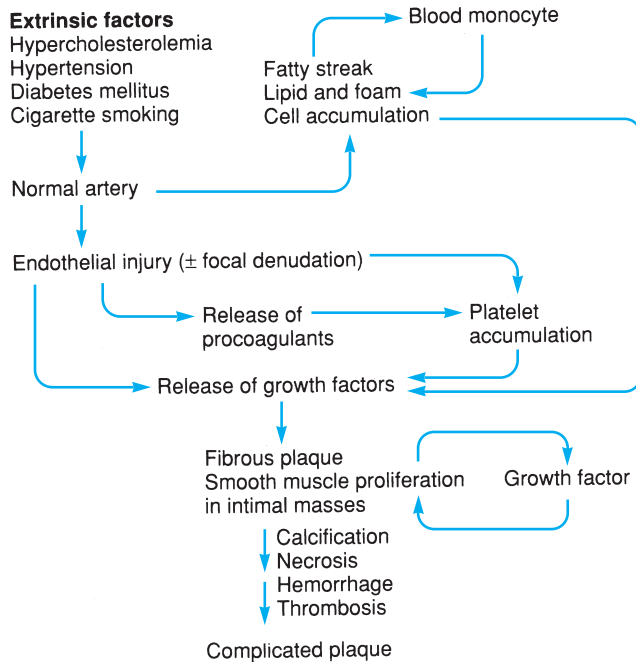

FIGURE 89.8. Atherogenesis and progression of atherosclerosis are probably the consequence of multiple factors acting on the arterial wall. (Adapted from Clowes AW. Theories of atherosclerosis. In: White RA, ed. *Atherosclerosis and Arteriosclerosis: Human Pathology and Experimental Animal Methods and Models*. Boca Raton, FL: CRC Press; 1989:3.)

Toll-like receptors are members of a larger superfamily of interleukin-1 receptors that share homology in their cytoplasmic region. There are 10 members of the TLR family identified, each with different ligands. Each member can activate distinct as well as overlapping signaling pathways, giving rise to different biologic effects. The individual ligands, as well as the location of the individual TLRs, are an active area of current research. It appears at this time that activation of TLRs is involved in the activation of the inflammatory cascade and possible initiator of plaque formation.¹⁷³

Inflammation appears to be a common factor in all theories of atherosclerosis, and more research is being performed in this area and isolating inflammatory mediators that may be involved.¹⁷⁴ Each of these hypotheses attempts to explain one or more aspects of atherogenesis. It is reasonable to conclude that each might be applicable at a different time during the development of the lesion (Fig. 89.8).

CHAPTER 90 ■ CEREBROVASCULAR OCCLUSIVE DISEASE

PETER H. LIN AND TAM T. HUYNH

KEY POINTS

- 1 Stroke remains the third most common cause of death in the United States, and atherosclerotic occlusive disease of the extracranial portion of the carotid artery is the most common cause of stroke.
- 2 Atherosclerosis is the pathologic process most often responsible for symptoms of cerebrovascular insufficiency.
- 3 Clinical risk factors for the development of carotid artery atherosclerotic lesions are the same as those for coronary artery disease: increased age, hypertension, diabetes mellitus, hyperlipidemia, hypercoagulable states, positive family history, and tobacco use.
- 4 Duplex ultrasound of the carotid artery is the preferred initial diagnostic study of choice to evaluate carotid occlusive disease.
- 5 The most common clinical presentations of extracranial cerebrovascular occlusive disease are transient ischemic attack (TIA) and hemispheric stroke.
- 6 The majority of asymptomatic and symptomatic carotid artery occlusive disease is caused by atherosclerosis. It is therefore important to modify risk factors to prevent progression of atherosclerotic disease.
- 7 Currently, carotid artery stenting should be limited to high-risk patients. The application of carotid artery stenting to patients at suitable risk to undergo endarterectomy should be limited to ongoing randomized clinical trials.

- 1 Carotid artery occlusive disease remains the most common cause of cerebrovascular accident, which represents the third most common cause of death in the United States.¹ The morbidity caused by a cerebrovascular accident is more disabling than that encountered with other ischemic conditions, including myocardial infarction or lower extremity ischemia. Neurologic sequelae related to cerebrovascular accident can include aphasia, paralysis, blindness, and weakness. These neurologic sequelae uniformly diminish the patient's ability to perform routine daily activities and invariably create an enormous burden with regard to health care costs. Consequently, prevention of a cerebrovascular accident, particularly the treatment of extracranial carotid occlusive disease, remains a paramount priority for all health care providers.

Atherosclerotic occlusive plaque at the origin of the internal carotid artery remains the most common cause of cerebrovascular accident. It is estimated that 40% to 60% of all ischemic strokes are related to atherosclerotic carotid bifurcation occlusive disease. Since the first reported case of carotid endarterectomy in 1954,² operative treatment of carotid occlusive disease has become one of the most commonly performed vascular operations in the United States. Various large, prospective, randomized clinical studies, which compared the efficacy of carotid endarterectomy plus optimal medical treatment with optimal medical treatment alone, have convincingly demonstrated the efficacy of carotid endarterectomy in reducing stroke and improving survival. The widely adopted endovascular therapy in the last decade has prompted interventional enthusiasts to establish a less invasive treatment alternative for cerebrovascular disease in selected patients. This chapter provides a comprehensive review of the epidemiology, pathophysiology, diagnosis, treatment, and relevant controversies in the management of cerebrovascular occlusive disease involving the carotid artery.

EPIDEMIOLOGY

Focal cerebral ischemic disease, or stroke, is responsible for 4.5 million deaths worldwide, with the majority occurring in nonindustrialized countries. Within the United States, it is estimated that more than 700,000 patients suffer a new or recurrent stroke annually.¹ Among them, approximately 200,000 die due to a consequence of stroke. Of the remaining survivors who suffer a stroke, two thirds are disabled and are never able to return to the workforce, while one third require prolonged hospitalization due to permanent disability. The cumulative economic burden of health care costs for these disabled patients with strokes is massive, exceeding \$16 trillion annually in the United States.¹

The term *cerebrovascular accident* (CVA) is often used interchangeably to refer to an ischemic stroke. A transient ischemic attack (TIA) is defined as a temporary focal cerebral or retinal hypoperfusion state that resolves spontaneously within 24 hours after its onset. However, the majority of TIAs resolve within minutes, and longer-lasting neurologic deficits more likely represent a stroke. The incidence of stroke is 0.2% per year in the general population but rises significantly with concurrent risk factors, age, sex, and ethnic background. Overall, the 20-year risk for a 45-year-old male is 3%, but this increases to 25% for a 40-year risk.³ The annual incidence of stroke doubles for each decade in patients older than 55 years of age. The largest incidence of stroke is observed in patients older than 80 years of age when the prevalence is 2%. In contrast, TIA occurs far more often in the younger population. In the United States, the prevalence of TIAs in males aged between 65 and 69 years is 2.7%, which increases markedly to 3.6% for males aged between 75 and 79 years.³

PATHOGENESIS OF STROKE

Approximately 85% of all strokes are caused by ischemic etiologies, while the remaining are caused by hemorrhagic disease. Hemorrhagic strokes can be caused by head trauma or spontaneous disruption of intracerebral blood vessels. Ischemic strokes are due to hypoperfusion from arterial occlusion or, less commonly, decreased flow resulting from proximal arterial stenosis and a poor collateral network. Patients with ischemic neurologic deficits can be further classified into having anterior or hemispheric symptoms and posterior or vertebrobasilar symptoms. The predominant causes of hemisphere symptoms arise from the occlusive lesion of the extracranial carotid artery, which may cause internal carotid artery thrombosis, flow-related ischemic events, and/or cerebral embolization. The risk factors for the development of carotid artery bifurcation disease are similar to those causing atherosclerotic occlusive disease in other vascular beds. Increasing age, male gender, hypertension, tobacco smoking, diabetes mellitus, homocysteinemia, and hyperlipidemia are well-known predisposing factors for the development of atherosclerotic occlusive disease.^{4,5} Etiologic factors that can contribute to the development of cerebral ischemia or infarction are listed in Table 90.1.

Stroke due to carotid bifurcation occlusive disease is usually related to atheroembolization (Fig. 90.1). The carotid bifurcation is an area of low flow velocity and low shear stress.

As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. Atherosclerotic plaque characteristically forms in the outer wall opposite to the flow divider (Fig. 90.2). Atherosclerotic plaque formation is complex, beginning with intimal injury, platelet deposition, smooth muscle cell proliferation, and fibroplasia, leading to subsequent luminal narrowing. With increasing degrees of stenosis in the internal carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates.

The tendency for atherosclerotic plaque to occur at the carotid bifurcation is also related to various factors, including vessel geometry, velocity profile, and shear stress. It has been demonstrated that plaque formation in the carotid artery bifurcation is increased within areas of low flow velocity and low shear stress and decreased in areas of high flow velocity and elevated shear stress. Postmortem specimens showed that atherosclerosis was particularly pronounced along the outer or lateral aspect of the proximal internal carotid artery and carotid bulb.⁶ This zone corresponds to areas of low velocity and low shear stress. Conversely, the medial or inner aspect of the cadaveric carotid bulb, which was associated with high blood flow velocity and high shear stress in the flow model, was relatively free of plaque formation.

The smooth muscle cell has an important role in the initial stages of plaque development. Smooth muscle cells migrate through the intima, proliferate within the media, and promote

FIGURE 90.1. Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli arising from the internal carotid artery, which provides the majority of blood flow to the cerebral hemisphere. With increasing degrees of stenosis in the carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates.

accumulation of cholesterol and other lipid molecules within the evolving lesion. Thereafter, the macrophage becomes a source of growth factor production that stimulates further smooth muscle cell proliferation and extracellular matrix production. Smooth muscle cells and macrophages initiate a secondary inflammatory cell reaction and are capable of ingesting lipid and of being transformed into vacuolated foam cells that are characteristic of atherosclerotic lesions.

In addition to these cellular components, the majority of carotid plaques have a necrotic core consisting of loose cellular debris and cholesterol crystals. The necrotic core is separated from the carotid lumen by a fibrous cap, which is composed of a rim of variable thickness comprising cellular components and extracellular matrix. The structural integrity of the fibrous cap is crucial to the final stage of plaque disruption and its clinical and pathologic sequelae. It is now generally accepted that acute changes within the plaque with exposure of the deeper lipid contents predispose toward thromboembolization. Another feature characteristic of advanced atherosclerotic plaques is intraplaque hemorrhage, which can occur in the absence of a disrupted fibrous cap. Symptomatic carotid disease is associated with increased neovascularization within the atherosclerotic plaque and fibrous cap. These vessels are larger and more irregular and may contribute to plaque instability and the onset of thromboembolic events.

CLINICAL MANIFESTATIONS OF CEREBRAL ISCHEMIA

A TIA is a focal loss of neurologic function, lasting for less than 24 hours. Crescendo TIAs refer to a syndrome consisting of repeated TIAs within a short period of time that is characterized by complete neurologic recovery in between. At a minimum, the term should probably be reserved for those with

FIGURE 90.2. A: The carotid bifurcation is an area of low flow velocity and low shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. B: The carotid atherosclerotic plaque typically forms in the outer wall opposite to the flow divider due in part to the effect of the low shear stress region, which also creates a transient reversal of flow during the cardiac cycle.

either daily events or multiple resolving attacks within 24 hours. Hemodynamic TIAs represent focal cerebral events that are aggravated by exercise or hemodynamic stress and typically occur after short bursts of physical activity, postprandially, or after getting out of a hot bath. It is implied that these are due to severe extracranial disease and poor intracranial collateral recruitment. Stroke in evolution refers to progressive worsening of the neurologic deficit, either linearly over a 24-hour period or interspersed with transient periods of stabilization and/or partial clinical improvement.⁷

The patients who suffer cerebrovascular accidents typically present with three categories of symptoms: ocular symptoms, sensory/motor deficit, and/or higher cortical dysfunction. The common ocular symptoms associated with extracranial carotid artery occlusive disease include amaurosis fugax and the presence of Hollenhorst plaques. Amaurosis fugax, commonly referred to as transient monocular blindness, is a temporary loss of vision in one eye, which patients typically describe as a window shutter coming down or gray shedding of the vision. This partial blindness usually lasts for a few minutes and then resolves. Most of these phenomena (>90%) are due to embolic occlusion of the main artery or the upper or lower divisions. Monocular blindness progressing over a 20-minute period suggests a migrainous etiology. Occasionally, the patient will recall no visual symptoms while the optician notes a yellowish plaque within the retinal vessels, which is also known as the Hollenhorst plaque. These are frequently derived from cholesterol embolization from the carotid bifurcation and warrant further investigation. Additionally, several ocular symptoms may be caused by microembolization from the extracranial carotid diseases including monocular visual loss due to retinal artery or optic nerve ischemia, the ocular ischemia syndrome, and visual field deficits secondary to cortical infarction and ischemia of the optic tracts. Typical motor and/or sensory symptoms associated with cerebrovascular accidents are lateralized or focal neurologic deficits. Ischemic events tend to have an abrupt onset, with the severity of the insult being apparent from the onset and not usually associated with seizures or paraesthesia. In contrast, they represent loss or diminution of neurologic function. Furthermore, motor or sensory deficits can be unilateral or bilateral, with the upper and lower limbs being variably affected depending on the site of the cerebral lesion. The combination of a motor and sensory deficit in the same body territory is suggestive of a cortical thromboembolic event, as opposed to lacunar lesions secondary to small-vessel disease of the penetrating arterioles. However, a small proportion of the latter may present with a sensorimotor stroke secondary to small-vessel occlusion within the posterior limb of the internal capsule. Pure sensory and motor strokes and those strokes where the weakness affects one limb only or does not involve the face are more typically seen with lacunar as opposed to cortical infarction. A number of higher cortical functions, including speech and language disturbances, can be affected by thromboembolic phenomena from the carotid artery; the most important clinical example for the dominant hemisphere is dysphasia or aphasia, while visuospatial neglect is an example of nondominant hemisphere injury.

DIAGNOSTIC EVALUATION

- 4 Duplex ultrasonography is the most widely used screening tool to evaluate for atherosclerotic plaque and stenosis of the extracranial carotid artery. It is also commonly used to monitor patients serially for progression of disease or after intervention (carotid endarterectomy or angioplasty). Duplex ultrasound of the carotid artery combines B-mode gray-scale imaging and Doppler waveform analysis. Characterization of the carotid plaque on gray-scale imaging provides useful information about its composition. However, there are currently no universal recommendations that can be made based solely on

the sonographic appearance of the plaque. On the other hand, criteria have been developed and well refined for grading the degree of carotid stenosis based primarily on Doppler-derived velocity waveforms.

The external carotid artery has a high-resistance flow pattern with a sharp systolic peak and a small amount of flow in diastole. In contrast, a normal internal carotid artery will have a low-resistance flow pattern with a broad systolic peak and a large amount of flow during diastole. The flow pattern in the common carotid artery resembles that in the internal carotid artery, as 80% of the flow is directed to the internal carotid artery, with waveforms that have broad systolic peaks and moderate amount of flow during diastole. Conventionally, velocity measurements are recorded in the common carotid artery, external carotid artery, carotid bulb, and the proximal, mid-, and distal portions of the internal carotid artery. Characteristically, the peak systolic velocity is increased at the site of the vessel stenosis. The end-diastolic velocity is increased with greater degrees of stenosis. In addition, stenosis of the internal carotid artery can lead to color shifts, with color mosaics indicating a poststenotic turbulence. Dampening of the Doppler velocity waveforms is typically seen in areas distal to severe carotid stenosis where blood flow is reduced. It is well known that occlusion of the ipsilateral internal carotid artery can lead to a “falsely” elevated velocity on the contralateral side due to an increase in compensatory blood flow. In the presence of a high-grade stenosis or occlusion of the internal carotid artery, the ipsilateral common carotid artery displays high-flow-resistance waveforms, similar to that seen in the external carotid artery. If there is a significant stenosis in the proximal common carotid artery, its waveforms may be dampened with low velocities.

The Doppler grading systems of carotid stenosis were initially established by comparison to angiographic findings of disease. Studies have shown variability in the measurements of the duplex properties by different laboratories, as well as heterogeneity in the patient population, study design, and techniques. One of the most commonly used classifications was established at the University of Washington School of Medicine in Seattle. Diameter reduction of 50% to 79% is defined by peak systolic velocity greater than 125 cm/s with extensive spectral broadening. For stenosis in the range of 80% to 99%, the peak systolic velocity is greater than 125 cm/s and peak diastolic velocity is greater than 140 cm/s.⁸ The ratio of internal carotid artery to common carotid artery (ICA/CCA) peak systolic velocity has also been part of various ultrasound diagnostic classifications. A ratio greater than 4 is a great predictor of angiographic stenosis of 70% to 99%. A multispecialty consensus panel has developed a set of criteria for grading carotid stenosis by duplex examination (Table 90.2).⁸

Magnetic resonance angiography (MRA) is increasingly being used to evaluate for atherosclerotic carotid occlusive disease and intracranial circulation. MRA is noninvasive and does not require iodinated contrast agents. MRA utilizes phase contrast or time-of-flight, with either two-dimensional or three-dimensional data sets for greater accuracy. Three-dimensional contrast-enhanced MRA allows data to be obtained in coronal and sagittal planes with improved image quality due to shorter study time. In addition, the new MRA techniques allow for better reformation of images in various planes to allow better grading of stenosis. There have been numerous studies comparing the sensitivity and specificity of MRA for carotid disease to duplex and selective contrast angiography.⁹ Magnetic resonance imaging (MRI) of the brain is essential in the assessment of acute stroke patients. MRI with diffusion-weighted imaging (DWI) can differentiate areas of acute ischemia, areas still at risk for ischemia (penumbra), and chronic cerebral ischemic changes. However, computed tomography (CT) imaging remains the most expeditious test in the evaluation of acute stroke patients to rule out intracerebral hemorrhage. Recently, multidetector computed tomography angiography (CTA) has gained

TABLE 90.2**CAROTID DUPLEX ULTRASOUND CRITERIA FOR GRADING INTERNAL CAROTID ARTERY STENOSIS**

■ DEGREE OF STENOSIS (%)	■ ICA PSV (cm/s)	■ ICA/CCA PSV RATIO	■ ICA EDV (cm/s)	■ PLAQUE ESTIMATE (%) ^a

increasing popularity in the evaluation of carotid disease.¹⁰ This imaging modality can provide volume rendering, which allows rotation of the object with accurate anatomic structures from all angles (Fig. 90.3). The advantages of CTA over MRA include faster data acquisition time and better spatial resolution. However, at the time of this writing, grading of carotid stenosis by CTA requires further validation before it can be widely applied.

Historically, digital subtraction angiography (DSA) has been the “gold standard” test to evaluate the extra- and intracranial circulation (Fig. 90.4). This is an invasive procedure, typically performed via a transfemoral puncture, and involves selective imaging of the carotid and vertebral arteries using iodinated contrast. The risk of stroke during cerebral angiography is generally reported at approximately 1% and is typically due to atheroembolization related to wire and catheter manipulation in the aortic arch or proximal branch vessels. Over the past decades, however, the incidence of neurologic complications following angiography has been reduced due to the use of improved guide wires and catheters, better-resolution digital imaging, and

increased experience. Local access complications of angiography are infrequent and include development of hematoma, pseudoaneurysm, distal embolization, or acute vessel thrombosis. Currently, selective angiography is particularly used for patients with suspected intracranial disease and for patients in whom percutaneous revascularization is considered. The techniques of carotid angioplasty and stenting for carotid bifurcation occlusive disease are described in detail later in this chapter. We generally use CTA or MRA to gather information about the aortic arch anatomy and presence of concomitant intracranial disease and collateral pathway in planning our strategy for carotid stenting or endarterectomy.

TREATMENT OF CAROTID OCCLUSIVE DISEASE

Conventionally, patients with carotid bifurcation occlusive disease are divided into two broad categories: patients without

FIGURE 90.3. A: Carotid computed tomography angiography is a valuable imaging modality that can provide a three-dimensional image reconstruction with high image resolution. A carotid artery occlusion is noted in the internal carotid artery (*arrow*). B: The entire segment of extracranial carotid artery is visualized from the thoracic compartment to the base of the skull.

FIGURE 90.4. A carotid angiogram with digital subtraction angiography reveals an ulcerated carotid plaque (*arrow*) in the proximal internal carotid artery, which also resulted in a high-grade internal carotid artery stenosis.

prior history of ipsilateral stroke or TIA (asymptomatic) and those with prior or current ipsilateral neurologic symptoms (symptomatic). It is estimated that 15% of all strokes are preceded by a TIA. The 90-day risk of a stroke in a patient presenting with a TIA is 3% to 17%.¹ According to the Cardiovascular Health Study, a longitudinal population-based study of coronary artery disease and stroke in men and women, the prevalence of TIA in men was 2.7% between the ages of 65 and 69 and 3.6% for ages 75 to 79; the prevalence in women was 1.4% and 4.1%, respectively.¹¹ There have been several studies reporting on the effectiveness of stroke prevention with medical treatment and carotid endarterectomy for symptomatic patients with moderate to severe carotid stenosis. Early and chronic aspirin therapy has been shown to reduce stroke recurrence rate in several large clinical trials.¹²

Symptomatic Carotid Stenosis

Currently, most neurologists prescribe both aspirin and clopidogrel for secondary stroke prevention in patients who have experienced a TIA or stroke.¹ In patients with symptomatic carotid stenosis, the degree of stenosis appears to be the most important predictor in determining risk for an ipsilateral stroke. The risk of a recurrent ipsilateral stroke in patients with severe carotid stenosis approaches 40%. Two large, multicenter, randomized clinical trials, the European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET), have both shown a significant risk reduction in stroke for patients with symptomatic high-grade stenosis (70% to 99%) undergoing carotid endarterectomy when compared to medical therapy alone.^{13,14} There has been much discussion regarding the different methodology used in the measurement of carotid stenosis and calculation of the life-table data between the two studies leading to similar results.¹⁵ Findings of these two landmark trials have also been

reanalyzed in many subsequent publications. The main conclusions of the trials remain validated and widely acknowledged. Briefly, the NASCET study showed that for high-grade carotid stenosis, the cumulative risk of ipsilateral stroke was 26% in the medically treated group and 9% in the surgically treated group at 2 years. For patients with moderate carotid artery stenosis (50% to 69%), the benefit of carotid endarterectomy is less but still favorable when compared to medical treatment alone; the 5-year fatal or nonfatal ipsilateral stroke rate was 16% in the surgically treated group versus 22% in the medically treated group.¹⁶ The risk of stroke was similar for the remaining group of symptomatic patients with less than 50% carotid stenosis, whether they had endarterectomy or medical treatment alone. The ECST reported similar stroke risk reduction for patients with severe symptomatic carotid stenosis and no benefit in patients with mild stenosis when carotid endarterectomy was performed versus medical therapy.¹⁴

The optimal timing of carotid intervention after acute stroke, however, remains debatable. Earlier studies showed an increased rate of postoperative stroke exacerbation and conversion of a bland to hemorrhagic infarction when carotid endarterectomy was carried out within 5 to 6 weeks after acute stroke. The dismal outcome reported in the early experience was likely related to poor patient selection. The rate of stroke recurrence is not insignificant during the interval period and may be reduced with early intervention for symptomatic carotid stenosis. Contemporary series have demonstrated acceptable low rates of perioperative complications in patients undergoing carotid endarterectomy within 4 weeks after acute stroke.¹⁶ In a recent retrospective series, carotid artery stenting when performed early (<2 weeks) after acute stroke was associated with higher mortality than when delayed (>2 weeks).¹⁷

Asymptomatic Carotid Stenosis

Whereas there is universal agreement that carotid revascularization (endarterectomy or stenting) is effective in secondary stroke prevention for patients with symptomatic moderate and severe carotid stenosis, the management of asymptomatic patients remains an important controversy. Generally, the detection of carotid stenosis in asymptomatic patients is related to the presence of a cervical bruit or based on screening duplex ultrasound findings. In one of the earlier observational studies, the authors showed that the annual occurrence rate of neurologic symptoms was 4% in a cohort of 167 patients with asymptomatic cervical bruits followed prospectively by serial carotid duplex scan.¹⁸ The mean annual rate of carotid stenosis progression to a greater than 50% stenosis was 8%. The presence of or progression to a greater than 80% stenosis correlated highly with the development of either a total occlusion of the internal carotid artery or new symptoms. The major risk factors associated with disease progression were cigarette smoking, diabetes mellitus, and age. This study supported the contention that it is prudent to follow a conservative course in the management of asymptomatic patients presenting with a cervical bruit.

One of the first randomized clinical trials on the treatment of asymptomatic carotid artery stenosis was the Asymptomatic Carotid Atherosclerosis Study (ACAS), which evaluated the benefits of medical management with antiplatelet therapy versus carotid endarterectomy.¹⁹ Over a 5-year period, the risk of ipsilateral stroke in individuals with a carotid artery stenosis greater than 60% was 5.1% in the surgical arm. On the other hand, the risk of ipsilateral stroke in patients treated with medical management was 11%. Carotid endarterectomy produced a relative risk reduction of 53% over medical management alone. The results of a larger randomized trial from Europe, the Asymptomatic Carotid Surgery Trial (ACST), recently confirmed similar beneficial stroke risk reduction for patients with asymptomatic greater than 70% carotid stenosis undergoing endarterectomy compared to medical therapy.²⁰ An important

point derived from this latter trial was that even with improved medical therapy, including the addition of statin drugs and clopidogrel, medical therapy was still inferior to endarterectomy in primary stroke prevention for patients with high-grade carotid artery stenosis. It is generally agreed that asymptomatic patients with severe carotid stenosis (80% to 99%) are at significantly increased risk for stroke and stand to benefit from either surgical or endovascular revascularization. However, revascularization for asymptomatic patients with a less severe degree of stenosis (60% to 79%) remains controversial.

CAROTID ENDARTERECTOMY VERSUS ANGIOPLASTY AND STENTING

7 Currently, medical therapy alone is inferior to surgical endarterectomy in stroke prevention for severe carotid stenosis. Now, the debate revolves around whether carotid angioplasty and stenting produces the same benefit that has been demonstrated by carotid endarterectomy. Since carotid artery stenting was approved by the Food and Drug Administration for clinical application in 2004, this percutaneous procedure has become a treatment alternative in patients who are deemed “high risk” for endarterectomy (Table 90.3). In contrast to many endovascular peripheral arterial interventions, percutaneous carotid stenting represents a much more challenging procedure, because it requires complex catheter-based skills utilizing a “0.014” guide wire system and distal embolic protection device. Moreover, current carotid stent devices predominantly utilize the monorail guide wire system, which requires more technical agility, in contrast to the over-the-wire catheter system that is routinely used in peripheral interventions. This percutaneous intervention often requires balloon angioplasty and stent placement through a long carotid guiding sheath via a groin approach. Poor technical skills can result in devastating treatment complications, such as stroke, which can occur due in part to plaque embolization during the balloon angioplasty and stenting of the carotid artery. Because of these various procedural components that require high technical proficiency, many early clinical investigations of carotid artery stenting, which included physicians with little or no carotid stenting experience, resulted in alarmingly poor clinical outcomes. A recent Cochrane review noted that, before 2006, a total of 1,269 patients had been studied in five randomized controlled trials comparing percutaneous carotid intervention and surgical carotid reconstruction.²¹ Taken together, these trials revealed that carotid artery stenting had a greater procedural risk of stroke and death when compared to carotid endarterectomy (odds ratio 1.33; 95% confidence interval [CI] 0.86–2.04).

Additionally, a greater incidence of carotid restenosis was noted in the stenting group than the endarterectomy cohorts. However, the constant improvement of endovascular devices, procedural techniques, and adjunctive pharmacologic therapy will likely improve the treatment success of percutaneous carotid intervention. Critical appraisals of these trials comparing the efficacy of carotid stenting versus endarterectomy are available for review.²² Several ongoing clinical trials will undoubtedly provide more insight on the efficacy of carotid stenting in the near future.

Surgical Techniques of Carotid Endarterectomy

Although carotid endarterectomy is one of the earliest vascular operations ever described and its techniques have been perfected in the last two decades, surgeons continue to debate many aspects of this procedure. For instance, there is no universal agreement with regard to the best anesthetic of choice, the best intraoperative cerebral monitoring, whether to “routinely” shunt, open versus eversion endarterectomy, and patch versus primary closure. Various anesthetic options are available for patients undergoing carotid endarterectomy, including general, local, and regional anesthesia. Typically, the anesthesia of choice depends on the preference of the surgeon, anesthesiologist, and patient. However, depending on the anesthetic given, the surgeon must decide whether intraoperative cerebral monitoring is necessary or intra-arterial carotid shunting will be used. In general, if the patient is awake, then his or her ability to respond to commands during the carotid clamp period determines the adequacy of collateral flow to the ipsilateral hemisphere. On the other hand, intraoperative electroencephalogram (EEG) or transcranial power Doppler (TCD) has been used to monitor for adequacy of cerebral perfusion during the clamp period for patients undergoing surgery under general anesthesia. Focal ipsilateral decreases in amplitudes and slowing of EEG waves are indicative of cerebral ischemia. Similarly, a decrease to less than 50% of baseline velocity in the ipsilateral middle cerebral artery is a sign of cerebral ischemia. For patients with poor collateral flow exhibiting signs of cerebral ischemia, intra-arterial carotid shunting with removal of the clamp will restore cerebral flow for the remaining part of the surgery. Stump pressures have also been used to determine the need for intra-arterial carotid shunting. Some surgeons prefer to shunt all patients on a routine basis and do not use intraoperative cerebral monitoring.

To perform a carotid endarterectomy, the patient’s neck is slightly hyperextended and turned to the contralateral side, with a roll placed between the shoulder blades. An oblique incision is made along the anterior border of the sternocleidomastoid

TABLE 90.3

muscle centered on top of the carotid bifurcation (Fig. 90.5). The platysma is divided completely. Typically, tributaries of the anterior jugular vein are ligated and divided. The dissection is carried medial to the sternocleidomastoid. The superior belly of the omohyoid muscle is usually encountered just anterior to the common carotid artery. This muscle can be divided. The carotid fascia is incised and the common carotid artery is exposed. The common carotid artery is mobilized cephalad toward the bifurcation. The dissection of the carotid bifurcation can cause reactive bradycardia related to stimulation of the carotid body. This reflex can be blunted with injection of 1% lidocaine into the carotid body or reversed with administration of intravenous atropine. A useful landmark in the dissection of the carotid bifurcation is the common facial vein. This vein can be ligated and divided. Frequently the 12th cranial nerve (hypoglossal nerve) traverses the carotid bifurcation just behind the common facial vein. The external carotid artery is mobilized just enough to get a clamp across. Often, a branch of the external carotid artery crossing to the sternocleidomastoid can be divided to allow further cephalad mobilization of the internal carotid artery. For high carotid bifurcations, division of the posterior belly of the digastric muscle is helpful in establishing distal exposure of the internal carotid artery.

Intravenous heparin sulfate (1 mg/kg) is routinely administered just prior to carotid clamping. The internal carotid artery is clamped first using a soft noncrushing vascular clamp to prevent distal embolization. The external and common carotid arteries are clamped subsequently. A longitudinal arteriotomy is made in the distal common carotid artery and extended into the bulb and past the occlusive plaque into the normal part of the internal carotid artery. Endarterectomy is carried out to remove the occlusive plaque (Fig. 90.6). If necessary, a temporary shunt can be inserted from the common carotid artery to

FIGURE 90.6. A: During carotid endarterectomy, vascular clamps are applied in the common carotid, external carotid, and internal carotid arteries. Carotid plaque is elevated from the carotid lumen. B: Carotid plaque is removed and the arteriotomy is closed either primarily or with a patch angioplasty.

FIGURE 90.7. A temporary carotid shunt is inserted from the common carotid artery (*long arrow*) to the internal carotid artery (*short arrow*) during carotid endarterectomy to provide continuous antegrade cerebral blood flow.

FIGURE 90.8. The distal transition line (*left side of the picture*) in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures (*arrows*) are placed when an intimal flap remains in this transition to ensure no obstruction to flow.

the internal carotid artery to maintain continuous antegrade cerebral blood flow (Fig. 90.7). Typically, a plane is teased out from the vessel wall and the entire plaque is elevated and removed. The distal transition line in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures are often placed when an intimal flap remains in this transition to ensure no obstruction to flow (Fig. 90.8). The occlusive plaque is usually removed from the origin of the external carotid artery using the eversion technique. The endarterectomized surface is then irrigated and any debris removed. A patch (autogenous saphenous vein; synthetic material, such as polyester or polytetrafluoroethylene; or biologic material) is sewn to close the arteriotomy (Fig. 90.9). Whether patch closure is necessary in all patients and which patch is the best remain controversial. However, most surgeons agree that patch closure is indicated particularly for the small vessel (<7 mm). The eversion technique has also been advocated for removing the plaque from the internal carotid artery. In the eversion technique, the internal carotid artery is transected at the bulb, the edges of the divided vessel are everted, and the occluding plaque is “peeled” off the vessel wall. The purported advantages of the eversion technique are no need for patch closure and a clear visualization of the distal transition area. Reported series have

not shown a clear superiority of one technique over the others.²³ Surgeons will likely continue to use the technique of their choice. Just prior to completion of the anastomosis to close the arteriotomy, the vessel is flushed of any potential debris. When the arteriotomy is closed, flow is restored to the external carotid artery first and to the internal carotid artery second. Intravenous protamine sulfate can be given to reverse the effect of heparin anticoagulation following carotid endarterectomy. The wound is closed in layers. After surgery, the patient’s neurologic condition is asserted in the operating room prior to transfer to the recovery area.

Complications of Carotid Endarterectomy

Most patients tolerate carotid endarterectomy very well and typically are discharged home within 24 hours after surgery. Complications after endarterectomy are infrequent but can be potentially life threatening or disabling. Acute ipsilateral stroke is a dreaded complication following carotid endarterectomy. Cerebral ischemia can be due to either intraoperative or postoperative events. Embolization from the occlusive plaque and prolonged cerebral ischemia are potential causes of intraoperative

FIGURE 90.9. A: An autologous or synthetic patch can be used to close the carotid arteriotomy incision, which maintains the luminal patency. B: A completion closure of carotid endarterectomy incision using a synthetic patch.

FIGURE 90.10. A: Carotid angiogram demonstrated a high-grade stenosis of the left internal carotid artery. B: Completion angiogram demonstrated a satisfactory result following a carotid stent placement.

stroke, with the most common cause of postoperative stroke being embolization. Less frequently, acute carotid artery occlusion can cause acute postoperative stroke. This is usually due to carotid artery thrombosis related to closure of the arteriotomy, an occluding intimal flap, or distal carotid dissection. When patients experience acute symptoms of neurologic ischemia after endarterectomy, immediate intervention may be indicated. Carotid duplex scan can be done expeditiously to assess patency of the extracranial internal carotid artery. Reexploration is mandated for acute carotid artery occlusion. Cerebral angiography can be useful if intracranial revascularization is considered.

Local complications related to surgery include excessive bleeding and cranial nerve palsies. Postoperative hematoma in the neck after carotid endarterectomy can lead to devastating airway compromise. Any expanding hematoma should be evacuated and active bleeding stopped. Securing an airway is critical and can be extremely difficult in patients with a large postoperative neck hematoma. The reported incidence of postoperative cranial nerve palsies after carotid endarterectomy varies from 1% to 30%.²⁴ Well-recognized injuries involve the marginal mandibular, vagus, hypoglossal, superior laryngeal, and recurrent laryngeal nerves. Often these are traction injuries, but they can also be due to severance of the nerve.

TABLE 90.4

UNFAVORABLE CAROTID ANGIOGRAPHIC APPEARANCE IN WHICH CAROTID STENTING SHOULD BE AVOIDED

- Extensive carotid calcification
- Polypoid or globular carotid lesions
- Severe tortuosity of the common carotid artery
- Long-segment stenoses (>2 cm in length)
- Carotid artery occlusion
- Severe intraluminal thrombus (angiographic defects)
- Extensive middle cerebral artery atherosclerosis

Techniques of Carotid Angioplasty and Stenting

Percutaneous carotid artery stenting has become an accepted alternative treatment in the management of “high-risk” patients with carotid bifurcation disease (Fig. 90.10). The perceived advantages of percutaneous carotid revascularization are related to the minimal invasiveness of the procedure compared to surgery. There are anatomic conditions based on angiographic evaluation in which carotid artery stenting should be avoided due to increased procedural-related risks (Table 90.4). In preparation for carotid stenting, the patient should be given oral clopidogrel 3 days prior to the intervention. The procedure is done in either the operating room with angiographic capabilities or in a dedicated angiography room. The patient is placed in the supine position. The patient’s blood pressure and cardiac rhythm are closely monitored.

To gain access to the carotid artery, a retrograde transfemoral approach is most commonly used as the access site for carotid intervention. Using the Seldinger technique, a diagnostic 5- or 6-French sheath is inserted in the common femoral artery. A diagnostic arch aortogram is obtained. The carotid artery to be treated is then selected using a 5-French diagnostic catheter and contrast is injected to show the carotid anatomy. It is important to assess the contralateral carotid artery, vertebrobasilar circulation, and intracranial circulation if these are not known based on the preoperative noninvasive studies. Once the decision is made to proceed with carotid artery stenting, with the tip of the diagnostic catheter still in the common carotid artery, a 0.035-inch 260-cm-long stiff glide wire is placed in the ipsilateral external carotid artery. Anticoagulation with intravenous bivalirudin bolus (0.75 mg/kg) followed by an infusion rate of 2.5 mg/kg/h or heparin (1 mg/kg) for the remainder of the procedure is routinely administered. Next, the diagnostic catheter is withdrawn and a 90-cm 6-French guiding sheath is advanced into the common carotid artery over the stiff glide wire. It is critical not to advance the sheath beyond the occlusive plaque in the carotid bulb. The stiff wire is then removed and preparation is made

to deploy the distal embolic protection device (EPD). Several distal EPDs are available (Table 90.5). The EPD device is carefully deployed beyond the target lesion. With regard to the carotid stent, there are several stents that have received approval from the Food and Drug Administration and are commercially available for carotid revascularization (Table 90.6). All current carotid stents use the rapid-exchange monorail 0.014-inch platform. The size selection is typically based on the size of the common carotid artery. Predilatation using a 4-mm balloon may be necessary to allow passage of the stent delivery catheter. Once the stent is deployed across the occlusive plaque, postdilatation is usually performed using a 5.5-mm or smaller balloon. It's noteworthy that balloon dilation of the carotid bulb may lead to immediate bradycardia due to stimulation of the glossopharyngeal nerve. The EPD is then retrieved and the procedure is completed with removal of the sheath from the femoral artery. The puncture site is closed using an available closure device or with manual compression. Throughout the procedure, the patient's neurologic function is closely monitored. The bivalirudin infusion is stopped or heparin is reversed with protamine, and the patient is maintained on clopidogrel (75 mg daily) for at least 1 month and on aspirin indefinitely.

Complications of Carotid Stenting

Although there have been no randomized trials comparing carotid stenting with and without EPD, the availability of embolic protection devices appears to have reduced the risk of distal embolization and stroke. The results of the various clinical trials and registries of carotid stenting have been reported and compared. It is well known that distal embolization as

detected by TCD is much more frequent with carotid stenting even with EPD when compared to carotid endarterectomy. However, the clinical significance of the distal embolization detected by TCD is not clear as most are asymptomatic. Acute carotid stent thrombosis is rare. The incidence of in-stent carotid restenosis is not well known but is estimated at 10% to 30%. Duplex surveillance frequently shows elevated peak systolic velocities within the stent after carotid stenting. However, velocity criteria are being formulated to determine the severity of in-stent restenosis after carotid stenting by duplex ultrasound.²⁵ It appears that systolic velocities exceeding 300 to 400 cm/s would represent greater than 70% to 80% restenosis. Bradycardia and hypotension occur in up to 20% of patients undergoing carotid stenting.²⁶ Systemic administration of atropine is usually effective in reversing the bradycardia. Other technical complications of carotid stenting are infrequent and include carotid artery dissection and access site complications, such as groin hematoma, femoral artery pseudoaneurysm, distal embolization, and acute femoral artery thrombosis.

NONATHEROSCLEROTIC DISEASE OF THE CAROTID ARTERY

Carotid Coil and Kink

A carotid coil consists of an excessive elongation of the internal carotid artery producing tortuosity of the vessel (Fig. 90.11). Embryologically, the carotid artery is derived from the third aortic arch and dorsal aortic root, and is uncoiled as the heart and great vessels descend into the mediastinum. In children,

TABLE 90.6**CURRENTLY APPROVED CAROTID STENTS IN THE UNITED STATES**

FIGURE 90.11. Excessive elongation of the carotid artery can result in carotid kinking (arrow), which can compromise cerebral blood flow and lead to cerebral ischemia.

FIGURE 90.12. A carotid fibromuscular dysplasia with typical characteristics of multiple stenosis with intervening aneurysmal outpouching dilatations. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue.

carotid coils appear to be congenital in origin. In contrast, elongation and kinking of the carotid artery in adults is associated with the loss of elasticity and an abrupt angulation of the vessel. Kinking is more common in women than men. Cerebral ischemic symptoms caused by kinks of the carotid artery are similar to those from atherosclerotic carotid lesions, but are more likely due to cerebral hypoperfusion than embolic episodes. Classically, sudden head rotation, flexion, or extension can accentuate the kink and provoke ischemic symptoms. Most carotid kinks and coils are found incidentally on carotid duplex scan. However, interpretation of the Doppler frequency shifts and spectral analysis in tortuous carotid arteries can be difficult because of the uncertain angle of insonation. Cerebral angiography, with multiple views taken in neck flexion, extension, and rotation, is useful in the determination of the clinical significance of kinks and coils.

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) usually involves medium-sized arteries that are long and have few branches (Fig. 90.12). Women in the fourth or fifth decade of life are more commonly affected than men. Hormonal effects on the vessel wall are thought to play a role in the pathogenesis of FMD. FMD of the carotid artery is commonly bilateral, and in about 20% of patients, the vertebral artery is also involved.²⁷ An intracranial saccular aneurysm of the carotid siphon or middle cerebral artery can be identified in up to 50% of the patients with FMD. Four histologic types of FMD have been described in the literature. The most common type is medial fibroplasias, which may present as a focal stenosis or multiple lesions with intervening aneurysmal outpouchings. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue. Commonly, mural dilations and microaneurysms can be seen

with this type of FMD. Medial hyperplasia is a rare type of FMD with the media demonstrating excessive amounts of smooth muscle. Intimal fibroplasia accounts for 5% of all cases and occurs equally in both sexes. The media and adventitia remain normal and there is accumulation of subendothelial mesenchymal cells with a loose matrix of connective tissue causing a focal stenosis in adults. Finally, premedial dysplasia represents a type of FMD with elastic tissue accumulating between the media and adventitia. FMD can also involve the renal and external iliac arteries. It is estimated that approximately 40% of patients with FMD present with a TIA due to embolization of platelet aggregates.²⁷ DSA demonstrates the characteristic “string of beads” pattern, which represents alternating segments of stenosis and dilatation. The string of beads can also be shown noninvasively by CTA or MRA. FMD should be suspected when an increased velocity is detected across a stenotic segment without associated atherosclerotic changes on carotid duplex ultrasound. Antiplatelet medication is the generally accepted therapy for asymptomatic lesions. Endovascular treatment is recommended for patients with documented lateralizing symptoms. Surgical correction is rarely indicated.

Carotid Artery Dissection

Dissection of the carotid artery accounts for approximately 20% of strokes in patients younger than 45 years of age. The etiology and pathogenesis of spontaneous carotid artery dissection remains incompletely understood. Arterial dissection involves hemorrhage within the media, which can extend into the subadventitial and subintimal layers. When the dissection extends into the subadventitial space, there is an increased risk of aneurysm formation. Subintimal dissections can lead to intramural clot or thrombosis. Traumatic dissection is typically

FIGURE 90.13. Carotid ultrasound reveals a patient with a carotid artery dissection in which carotid flow is separated in the true flow lumen (long arrow) from the false lumen (short arrow).

the result of hyperextension of the neck during blunt trauma, neck manipulation, strangulation, or penetrating injuries to the neck. Even in supposedly spontaneous cases, a history of preceding unrecognized minor neck trauma is not uncommon. Connective disorders, such as Ehlers-Danlos syndrome, Marfan syndrome, α_1 -antitrypsin deficiency, and fibromuscular dysplasia, may predispose to carotid artery dissection. Iatrogenic dissections can also occur due to catheter manipulation or balloon angioplasty.

Typical clinical features of carotid artery dissection include unilateral neck pain, headache, and ipsilateral Horner syndrome in up to 50% of patients, followed by manifestations of cerebral or ocular ischemia and cranial nerve palsies. Neurologic deficits can result because of either hemodynamic failure (caused by luminal stenosis) or an artery-to-artery thromboembolism. The ischemia may cause TIAs or infarctions, or both. Catheter angiography has been the method of choice to diagnose arterial dissections, but with the advent of duplex ultrasonography, MRI/MRA, and CTA, most dissections can now be diagnosed using noninvasive imaging modalities (Fig. 90.13). The dissection typically starts in the internal carotid artery

distal to the bulb. Uncommonly, the dissection can start in the common carotid artery or be an extension of a more proximal aortic dissection. Medical therapy has been the accepted primary treatment of symptomatic carotid artery dissection. Anti-coagulation (heparin and warfarin) and antiplatelet therapy have been commonly used, although there have not been any randomized studies to evaluate their effectiveness. The prognosis depends on the severity of the neurologic deficit but is generally good in extracranial dissections. The recurrence rate is low. Therapeutic interventions have been reserved for recurrent TIAs or strokes or failure of medical treatment. Endovascular options include intra-arterial stenting, coiling of associated pseudoaneurysms, or, more recently, deployment of covered stents.

Carotid Artery Aneurysms

Carotid artery aneurysms are rare, encountered in less than 1% of all carotid operations (Fig. 90.14). The true carotid artery aneurysm is generally due to atherosclerosis or medial degeneration. The carotid bulb is involved in most carotid aneurysms, and bilaterality is present in 12% of patients. Patients typically present with a pulsatile neck mass. The available data suggest that, untreated, these aneurysms lead to neurologic symptoms from embolization. Thrombosis and rupture of the carotid aneurysm are rare. Pseudoaneurysms of the carotid artery can result from injury or infection. Mycotic aneurysms often involve a past history of syphilis but are now more commonly associated with peritonsillar abscesses caused by *Staphylococcus aureus* infection. Fibromuscular dysplasia and spontaneous dissection of the carotid artery can lead to the formation of true aneurysms or pseudoaneurysms. Whereas conventional surgery has been the primary mode of treatment in the past, carotid aneurysms are currently being treated more commonly using endovascular approaches.²⁸

Carotid Body Tumor

The carotid body originates from the third branchial arch and from neuroectodermal-derived neural crest lineage. The

FIGURE 90.14. A: An anteroposterior angiogram of the neck revealing a carotid artery aneurysm. B: A lateral projection of the carotid artery aneurysm. C: Following endovascular stent graft placement, the carotid artery aneurysm is successfully excluded.

FIGURE 90.15. A: A carotid body tumor (arrow) located adjacent to the carotid bulb. B: Following periadventitial dissection, the carotid body tumor is removed.

normal carotid body is located in the adventitia or periadventitial tissue at the bifurcation of the common carotid artery (Fig. 90.15). The gland is innervated by the glossopharyngeal nerve. Its blood supply is derived predominantly from the external carotid artery but can also come from the vertebral artery. Carotid body tumor is a rare lesion of the neuroendocrine system. Other glands of neural crest origin are seen in the neck, parapharyngeal spaces, mediastinum, retroperitoneum, and adrenal medulla. Tumors involving these structures have been referred to as paraganglioma, glomus tumor, or chemodectoma. Approximately 5% to 7% of carotid body tumors are malignant. Although chronic hypoxemia has been invoked as a stimulus for hyperplasia of the carotid body, approximately 35% of carotid body tumors are hereditary. The risk of malignancy is greatest in young patients with familial tumors.

Symptoms related to the endocrine products of the carotid body tumor are rare. Patients usually present between the fifth and seventh decades of life with an asymptomatic lateral neck mass. The diagnosis of carotid body tumor requires confirmation on imaging studies. Carotid duplex scanning can localize the tumor to the carotid bifurcation, but CT or MRI is usually required to further delineate the relationship of the tumor to the adjacent structures. Classically, a carotid body tumor will widen the carotid bifurcation. The Shamblin classification describes the tumor extent: I, tumor is less than 5 cm and relatively free of vessel involvement; II, tumor is intimately involved but does not encase the vessel wall; and III, tumor is intramural and encases the carotid vessels and adjacent nerves.²⁹ With good-resolution CT and MRI, arteriography is usually not required. However, arteriography can provide an assessment of vessel invasion and intracranial circulation, and allows for preoperative embolization of feeder vessels, which has been reported to reduce intraoperative blood loss. Surgical resection is the recommended treatment for suspected carotid body tumor.

Carotid Trauma

Blunt or penetrating trauma to the neck can cause injury to the carotid artery. Notwithstanding the massive bleeding from

carotid artery transection, injury to the carotid artery can result in carotid dissection, thrombosis, or pseudoaneurysm formation. Carotid duplex ultrasound can be useful to locate the site of injury in the cervical segment of the carotid artery. Spiral CTA has become the modality of choice to detect extracranial carotid artery injury. Confirmation of carotid injury by contrast cerebral angiography remains the “gold standard” diagnostic test. Injuries to the cervical segment of the common and internal carotid arteries can be repaired surgically. Acute carotid artery thrombosis is usually treated medically with anticoagulation if the patient is asymptomatic. Revascularization should be considered for patients presenting with ongoing cerebral ischemia related to carotid artery thrombosis. Traumatic carotid artery dissection can cause cerebral ischemia due to thromboembolization, decreased flow, or thrombosis. Commonly, the dissection involves the distal portion of the cervical and petrous segment of the internal carotid artery. Medical management with antiplatelet or anticoagulation therapy is usually adequate for uncomplicated traumatic carotid dissection. In patients with pseudoaneurysms of the carotid artery that are located in a segment that is out of surgical reach, the use of selective coil embolization of the pseudoaneurysm or exclusion of the pseudoaneurysm by a covered stent graft has been reported. Bare-metal stents have been used with success in the treatment of traumatic carotid artery dissection.

CHAPTER 91 ■ UPPER EXTREMITY ARTERIAL DISEASE

MARK D. MORASCH

KEY POINTS

- 1 Presenting symptoms of upper extremity occlusive disease include evidence of arterial emboli, Raynaud phenomenon, pain, and exercise-related forearm fatigue.
- 2 Physical examination should include the thoracic outlet and the entire upper extremity.
- 3 In severe bilateral hand ischemia, a systemic cause of the arterial lesions should be sought.
- 4 Several noninvasive tests, including plethysmography, transcutaneous Doppler examination, and duplex scan, are available for the objective evaluation of patients with upper extremity ischemia.
- 5 Atherosclerosis is the most common cause of upper extremity occlusive lesions.
- 6 Thoracic outlet syndrome is the most common condition producing upper extremity vascular complications in young adults.

In the upper extremity, a broad spectrum of arterial occlusive processes can lead to ischemic symptoms. An accurate diagnosis requires obtaining a very thorough patient history, performing careful physical examination, and applying the liberal use of ancillary testing. Appropriate endovascular or open surgical intervention depends on the location of the vascular lesion and the nature of the underlying occlusive process.

ANATOMY

The supra-aortic vessels normally develop as three separate trunks taking origin from the arch of the aorta within the superior mediastinum. The conventional definition includes the innominate artery, the subclavian arteries to involve the origins of the vertebral arteries, and the common carotid arteries proximal to their bifurcations. The left subclavian artery is the third

of three trunks and it originates posterior to and to the left of the left common carotid. There may be as few as one great vessel or as many as six arising from the transverse aorta.¹ The most common variation is the bovine-type aortic arch, where the first and second branches arise from a common ostium (16%) or as a single trunk (8%). The arch configuration with an aberrant right subclavian artery that arises as the fourth of four vessels occurs in approximately 0.5% of individuals.^{2,3}

The subclavian artery crosses the thoracic outlet and becomes the axillary artery. As the continuation of the subclavian, the axillary vessel commences at the outer border of the first rib and ends at the lower border of the teres major tendon. Beyond the teres major tendon, the axillary becomes the brachial artery, which runs medial to the humerus. At the bend of the elbow, the brachial artery lies midway between its two epicondyles, and below the bend of the elbow, it divides into the radial and ulnar arteries.

FIGURE 91.1. Incomplete palmar arch and ulnar dominant anatomy. Given radial artery occlusion, the thumb and forefinger are poorly perfused.

The anatomic variability of the upper extremity arteries, especially the palmar arches (superficial and deep), is well known,⁴ and incomplete palmar arches (Fig. 91.1) play a significant role in ischemic disease. The deep palmar arch is formed by the terminal part of the radial artery and the superficial arch by the ulnar artery. In a study of 500 hand arteriograms, the deep palmar arch appeared complete in 95.2% of cases.⁵ Because the ulnar artery predominates in supplying blood to the hand, the completeness of the superficial palmar arch is the determining factor in hand ischemia. In contrast to the deep arch, the superficial palmar arch exhibits many variations (Fig. 91.2). Six types of complete arch are known; a complete superficial palmar arch was seen in only 42.4% of cases in the angiographic study.⁵

MEDICAL HISTORY

Obtaining an appropriate patient history is an extremely important initial step in arriving at a diagnosis in patients with

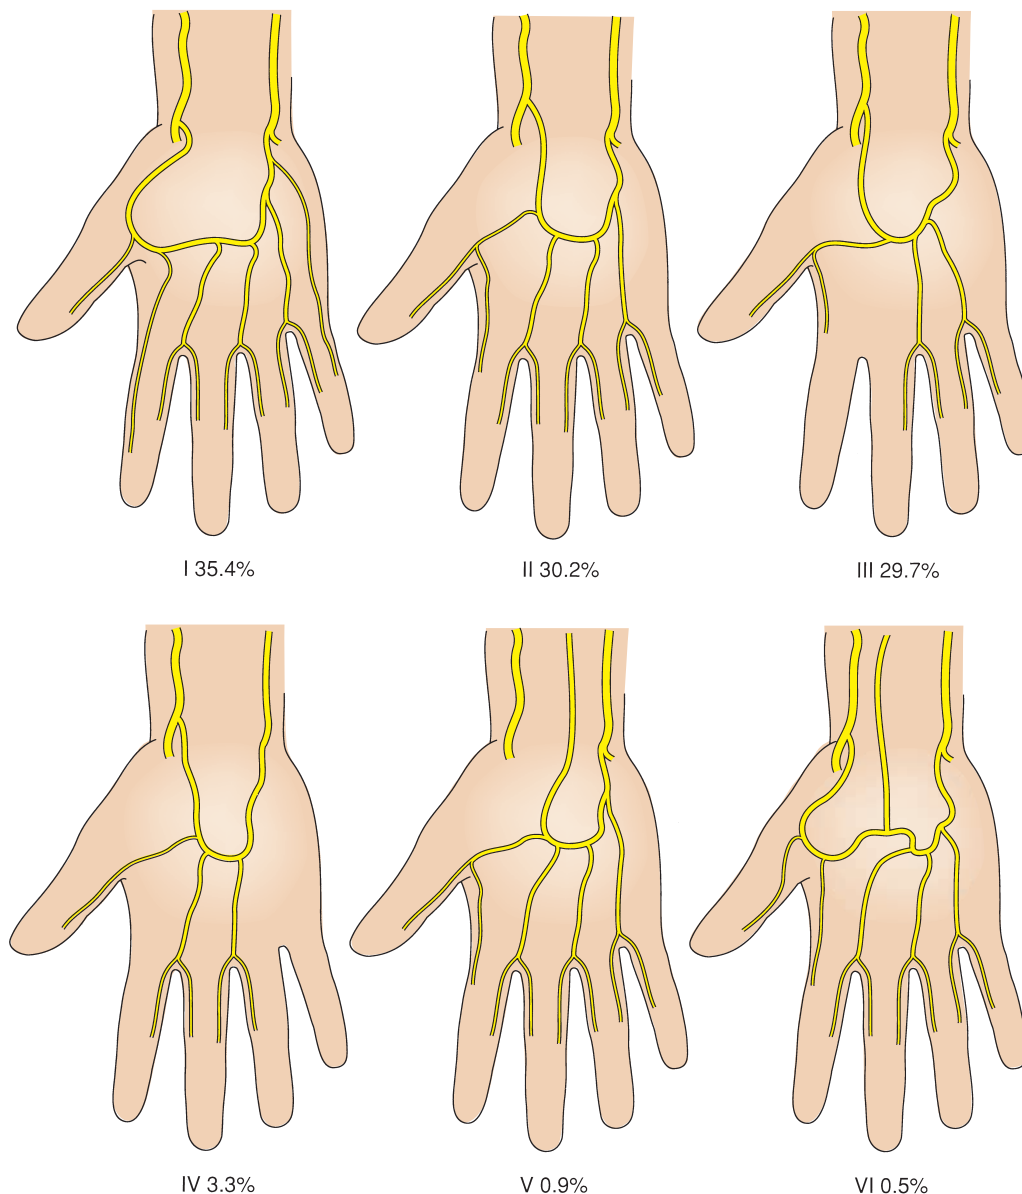

FIGURE 91.2. Different types of complete superficial palmar arch found on 500 hand arteriograms. (Reproduced with permission from Janevski BK. *Angiography of the Upper Extremity*. Amsterdam, The Netherlands: Martinus Nijhoff; 1982.)

TABLE 91.1**ETIOLOGY****CONDITIONS AND RISKS FOR UPPER EXTREMITY ISCHEMIA**

Occupational injury	Medical conditions
Vibration syndrome	Atherosclerosis
Pneumatic tools	Arteritis
Chainsaws	Collagen disease
Grinders	Scleroderma
Electrical burns	Rheumatic arteritis
Hypothenar hammer syndrome	Systemic lupus erythematosus
Mechanical work or auto repair	Dermatomyositis
Lathe operation	Allergic necrotizing arteritis
Carpentry	Takayasu disease
Electrical work	Giant cell arteritis
Occupational acroosteolysis—polyvinylchloride exposure	Blood dyscrasias
Athletic activities	Cold agglutinins
Thoracic outlet compression	Cryoglobulins
Baseball pitching	Polycythemia vera
Kayaking	Behçet syndrome
Weight lifting	Antiphospholipid syndrome
Rowing	Thoracic outlet syndrome
Butterfly swimming	Congenital arterial wall defects
Golfing	Pseudoxanthoma elasticum
Hand ischemia	Ehlers-Danlos syndrome
Baseball catching	Fibromuscular dysplasia
Frisbee	Iatrogenic injury
Karate	Arterial blood gas and pressure monitoring
Handball	Cardiac catheterization
Pharmacologic history	Arteriography
Ergot poisoning	Frostbite
Beta-blockers	Renal transplantation and related problems
Drug abuse, cocaine use	Azotemic arteriopathy
Cytotoxic drugs	Hemodialysis shunts
Dopamine overdose	Radiation
	Breast carcinoma
	Hodgkin disease
	Aneurysms of the upper extremity

upper extremity ischemia. In addition to a careful delineation of symptoms, appropriate inquiries include occupational, pharmacologic, and athletic risks and a pertinent medical history. Table 91.1 lists conditions and activities that can be related to the development of upper extremity ischemic symptoms.

SIGNS AND SYMPTOMS

- 1 Presenting signs and symptoms of upper extremity occlusive disease can include digital gangrene, evidence of arterial emboli, persistent wounds, Raynaud phenomenon, pain, and exercise-related forearm fatigue. Signs of embolic phenomena include gangrene of the tips of the fingers, petechiae of the skin, splinter hemorrhages of the nail bed, and livedo reticularis.

The term *Raynaud phenomenon* refers to episodic digital color changes provoked by stimuli, such as cold or emotion. The digits first exhibit pallor, then cyanosis, and finally rubor. The pathophysiology of the color changes from white to blue to red is thought to be digital ischemia (resulting from

vasospasm), followed by desaturation of hemoglobin (which produces cyanosis), and finally a reactive hyperemia. Raynaud phenomenon should not be confused with Raynaud disease. The former is a secondary process, whereas the latter is a primary disease without a known cause. The diagnosis of primary Raynaud disease is made only after all the etiologic factors listed in Table 91.1 have been excluded and after symptoms persist for at least 2 years. In patients with unilateral Raynaud phenomenon, organic arterial occlusive disease should be suspected. In contrast, bilateral symptoms are often the consequence of a systemic process that causes vasospasm. Raynaud phenomenon should also be distinguished from acrocyanosis, a disorder characterized by painless, persistent, diffuse cyanosis of the fingers and hands.

CLINICAL EXAMINATION

Large-artery occlusion is usually not difficult to diagnose. Careful pulse examination will usually confirm the diagnosis.

Distal arterial lesions causing hand or finger ischemia can be more difficult to delineate.

- 2 Physical examination should include the thoracic outlet and the entire upper extremity. Bilateral brachial artery cuff pressure measurement and auscultation for subclavian bruits should be performed at every initial patient encounter. Palpation of the supraclavicular region may detect a subclavian artery aneurysm or a cervical rib. Auscultation with the stethoscope placed in the supraclavicular region and in the infraclavicular fossae while listening for a bruit with the patient's arm placed in both neutral and hyperabducted positions can help to establish the diagnosis of thoracic outlet compression. Pulse examination begins with the subclavian artery in the supraclavicular fossa and continues with the axillary artery under the armpit, the brachial artery at the upper arm and elbow, and the radial and ulnar arteries at the wrist level. A decreased or absent pulse in any site other than the supraclavicular fossa indicates more proximal occlusion. Conversely, a readily palpable pulse in the supraclavicular fossa may represent a subclavian artery aneurysm.

Complete examination includes an Allen test. The radial and ulnar arteries of one wrist are compressed tightly by the examiner's fingers. The patient then opens and closes the hand until the hand is devoid of blood. The fingers are extended and either the radial or the ulnar artery is released. The hand is observed for capillary return of color. The test result is judged normal if refilling of both sides of the hand is complete within a short period. If a portion of the hand does not reperfuse, continuity of the palmar vascular arch is incomplete. Examination of the hand should also include palpation of the palm for aneurysms.

LABORATORY TESTING

- 3 In severe bilateral hand ischemia, a systemic cause for occlusion should be sought. Laboratory tests (Table 91.2) include serologic, immunologic, and hematologic studies to help establish the diagnosis.

The erythrocyte sedimentation rate can be a useful screening test to aid in the diagnosis of various forms of arteritis. A positive antinuclear antibody test result suggests connective tissue disease or other arteritides. When the antinuclear antibody titer is abnormal, immunofluorescent pattern analysis of antibodies can help to establish the diagnosis of various connective tissue disorders. The speckled pattern antibody is more specific for systemic lupus erythematosus. A nucleolar pattern suggests scleroderma. A positive anticardiolipin antibody is diagnostic for antiphospholipid syndrome, which is characterized by thromboembolic events in young adults.⁶

IMAGING

Along with laboratory testing, a combination of noninvasive vascular imaging and radiologic testing may be needed to establish the proper diagnosis. Plain radiographs can be helpful in delineating systemic disease. Soft tissue radiographs of the hand may reveal calcinosis seen in the CREST (calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia) syndrome or diffuse calcified arteries noted in diabetic or azotemic arteriopathy (Fig. 91.3). A chest film can detect pulmonary fibrosis consistent with systemic sclerosis or bony anomalies of the thoracic outlet, such as cervical ribs (Fig. 91.4), anomalous first ribs, or healed fractures of the first rib or clavicle.

- 4 Several noninvasive tests, including plethysmography, transcutaneous Doppler examination, and duplex scan, are available for the objective evaluation of patients with upper extremity ischemia.⁷ Doppler examination consists of audible signal interpretation, waveform recording with spectral analysis, and systolic pressure measurements. Bilateral examinations should be performed for comparative purposes. Systemic diseases will usually result in bilateral abnormalities, while unilateral disease indicates a more focal problem such as embolic occlusion or unilateral aneurysm.

Doppler is helpful in determining the patency of the ulnar artery, which may be difficult to palpate. In the hand, Doppler examination of the palmar arches is performed best at the midthenar and hypothenar regions. The common digital vessels should be examined at the base of the fingers, where they

FIGURE 91.3. Typical appearance of azotemic arteriopathy (calciophylaxis) in a diabetic patient with a renal transplant. All the digital arteries are distinctly seen on plain film. The radial artery has a “lead pipe” appearance. An arteriogram shows multiple digital artery occlusions. (Reproduced with permission from Yao JST. Arterial surgery of the upper extremity. In: Haimovici H, Callow AD, DePalma RG, et al., eds. *Vascular Surgery: Principles and Techniques*, 3rd ed. Norwalk, CT: Appleton & Lange; 1989:863.)

FIGURE 91.4. Cervical rib (*arrow*) in a patient with subclavian artery aneurysm caused by thoracic outlet compression.

divide into the proper digital arteries. The use of noninvasive testing to detect digital artery occlusion helps distinguish Raynaud phenomenon from disease and can pinpoint the sites of occlusive lesions.

Segmental upper extremity pressures commence with a pneumatic cuff placed on the upper arm as in routine blood pressure recording. The brachial recording reflects the pressure in all arteries proximal to the cuff. A difference of greater than 10 to 20 mm Hg compared to the other arm signifies innominate, subclavian, axillary, or brachial artery stenosis. The cuff is next applied to the forearm with the radial artery used for signal detection. A pressure drop of 20 to 30 mm Hg signifies an obstruction distal to the brachial artery. Finger pressures are measured using a 2.5-cm cuff placed at the base of the digit. Return of Doppler signals after cuff deflation is monitored at the fingertip. An arterial occlusion distal to the palmar arch is defined by a pressure gradient between the fingers of more than 15 mm Hg or a wrist-to-digit difference of 30 mm Hg. The Doppler technique is of particular value in determining palmar arch patency in a patient who is unconscious or uncooperative with an Allen test. Before arterial line placement, this simple test may help to avoid hand ischemia.

Plethysmography is used to record finger pulse contours for analysis and to differentiate between a normal state and obstructive or vasospastic disease.⁷ The duplex scan is helpful in establishing the diagnosis of aneurysm.

Imaging using traditional catheter-directed contrast injection should be performed bilaterally and include all arteries from the aortic arch to the hand. Multiplanar angiographic views of the aortic arch utilizing digital subtraction angiography are useful for planning proximal vessel revascularization. Specific emphasis should be placed on the vessel's origins with delayed views to show vascular reconstitution from steal. Arteriography is useful in defining the vascular anatomy of the hand. The use of intra-arterial vasodilators can help break spasm and lead to better delineation of the smallest hand vessels.

FIGURE 91.5. Focused magnetic resonance angiogram of the hand.

Magnetic resonance and computed tomography (CT) angiography provide multiplanar images of the proximal vessels that rival those of biplanar digital subtraction angiography. Gadolinium-enhanced magnetic resonance angiography and certain noncontrast magnetic resonance imaging sequences are being developed for the vessels in the hand (Fig. 91.5). CT scanning provides information regarding the extent of calcification in the aortic arch and can help delineate adjacent bony structures and their relationship to the vessels (Fig. 91.6). Transesophageal echocardiography (TEE) is used to assess myocardial function, to rule out a cardioembolic source, and, like CT, to identify significant calcific lesions or atheromata within the arch.

Proximal Arterial Lesions

- 5 Atherosclerosis is the most common disease affecting the supra-aortic trunk vessels. The first part of the subclavian artery is the most frequent site of involvement. The innominate artery is also a common site of disease. Lesions include total occlusion with or without associated steal phenomena, high-grade stenoses, and ulcerating plaques, which may be the source of emboli.

FIGURE 91.6. Thoracic outlet computed tomography scan showing bony relationship.

FIGURE 91.7. Large subclavian artery aneurysm.

Occlusive lesions less commonly result from congenital anomalies, arteritis, or exposure to therapeutic radiation. More distally, the subclavian arteries can be damaged from dissection, aneurysm, or the long-term effects of thoracic outlet syndrome. Symptoms from nonatherosclerotic processes account for less than 20% of the disease that requires intervention.^{8–12} The more common atherosclerotic lesions tend to cause occlusive and embolic symptoms equally, while vessel obliteration from arteritis tends only to cause symptoms related to hemodynamic insufficiency.

Single-vessel atherosclerotic occlusive disease involving the great vessels is often seen in younger adults (fifth decade), while patients with extensive or multiple trunk involvement tend to be older. Cigarette smoking is certainly a significant risk factor for the development of atherosclerotic occlusive disease involving these vessels.

Subclavian artery aneurysms can develop proximally (intrathoracic aneurysms) or distally (extrathoracic aneurysms). Extrathoracic subclavian artery aneurysms usually develop distal to the vertebral artery origin and present in the form of a poststenotic dilatation or as the result of repetitive trauma to the artery in patients with arterial thoracic outlet syn-

drome¹³ (Fig. 91.7). Causes of proximal subclavian artery aneurysm formation include atherosclerosis, infection (including those that are the result of syphilis or tuberculosis), cystic medial necrosis, Marfan syndrome, and a few other rare genetic disorders. Subclavian artery aneurysms have the potential to thrombose, embolize, and cause symptoms from local compression or rupture.

Forms of arteritis producing upper extremity ischemic symptoms include such diverse processes as Takayasu arteritis, giant cell arteritis, temporal arteritis, and polymyalgia rheumatica. Takayasu arteritis is a nonspecific inflammatory process that segmentally affects the aorta and its main branches. The process can involve the carotid, subclavian, axillary, and pulmonary arteries.¹⁴ Takayasu arteritis frequently involves all three great vessels proximally. The true etiology of this nonspecific inflammatory disease has not been elucidated, but it is known to predominantly affect women in their second or third decades of life. The arteriographic appearance is often diagnostic. The tapered involvement of multiple arteries and a well-developed network of collaterals are characteristic. The pulmonary artery will be affected in 45% of patients. The hypertrophic occlusive lesions of Takayasu disease carry low embolic potential, and most symptoms relate to low flow as the disease progresses to multi-vessel occlusion (Fig. 91.8). The histopathologic appearance of the lesions depends on the phase of the disease. They appear intensely inflammatory during the acute phase and more sclerotic when the disease is “burned out.” The inflammatory process is characterized by fibrosis and thickening of the arterial wall with pathologic changes usually most noticeable in the adventitial and medial layers of the involved vessels. Aneurysmal changes with embolic potential can develop during the chronic phase of the disease.

Giant cell arteritis can involve the more distal subclavian arteries and may be differentiated from Takayasu arteritis by location and by the fact that it affects an older patient population. Characteristic arteriographic findings include long segments of smooth stenosis or occlusion alternating with areas of normal or dilated artery and the absence of irregular plaques or ulceration (Fig. 91.9). The most frequently recognized clinical features of giant cell arteritis (cranial, temporal, and granulomatous arteritis) are related to involvement of the cranial arteries. The subclavian and axillary arteries are

FIGURE 91.8. Young woman with severe, symptomatic Takayasu arteritis. (Reproduced with permission from Berguer R, Keiffer E. *Surgery of the Arteries to the Head*. New York: Springer-Verlag; 1992.)

FIGURE 91.9. Characteristic long, segmental narrowing of the subclavian artery in a patient with giant cell arteritis. (Reproduced with permission from Yao JST. Arterial surgery of the upper extremity. In: Haimovici H, Callow AD, DePalma RG, et al., eds. *Vascular Surgery: Principles and Techniques*, 3rd ed. Norwalk, CT: Appleton & Lange; 1989:858.)

common sites of involvement.¹⁵ In addition to upper extremity ischemic symptoms, patients with arteritis often present with fever, malaise, headache, and joint pain. The erythrocyte sedimentation rate is often elevated. The results of serologic tests may be positive, but none is sufficiently sensitive or specific to be considered diagnostic.

The subclavian artery can develop an accelerated form of atherosclerosis as a result of radiation injury (Fig. 91.10). The rate at which the process develops depends on the radiation dose and may follow radiotherapy for, among other diseases, breast cancer, intrathoracic tumors, or Hodgkin lymphoma.

6 Thoracic outlet syndrome is the most common condition producing upper extremity vascular complications in young adults. Possible sites of compression include the costoclavicular space, formed by the first thoracic rib and clavicle (Fig. 91.11); the interscalene triangle; the angle between the insertion of the pectoralis minor tendon and the coracoid process in the axilla; and the head of the humerus in extreme external rotation. Thoracic outlet compression may be caused by bony anomalies, such as a cervical rib or an abnormal first thoracic rib, or it may be secondary to hypertrophy of the anterior scalene muscle. Although a cervical rib is found in 0.5% to 1% of the population, fewer than 10% of such persons have symptoms of neurovascular compression (Fig. 91.12). Arterial complications include subclavian aneurysm formation, poststenotic dilation, thrombosis, and distal embolisms.

Aneurysmal changes can also develop in either the anterior or, more commonly, the posterior circumflex humeral arteries due to repetitive athletic activities. Tethering of the axillary artery between the chest and the loop of circumflex arteries, around the humeral neck, can lead to traction injuries. Intimal damage, subsequent thrombosis, or aneurysm formation can result. Continued excessive arm activity can result in distal embolization as clot is extruded from these side branch aneurysms.^{16–19} Aneurysm formation in the suprascapular and subscapular arteries has also been reported.¹⁷ Direct trauma

FIGURE 91.10. Severe arterial damage following high-dose cervical thoracic irradiation.

from the head of the humerus can also cause compression to the axillary artery with similar sequelae.^{19,20}

Distal Arterial Lesions

Several collagen vascular disorders can produce systemic signs as well as upper extremity symptoms ranging from

FIGURE 91.11. Thoracic outlet computed tomography scan.

FIGURE 91.12. Arteriogram in a patient with subclavian artery aneurysm (*black arrows*) caused by a cervical rib. Multiple distal arterial occlusions have developed as a result of embolism (*white arrow*).

Raynaud phenomenon to gangrene of the digits. These disorders include scleroderma, rheumatoid arthritis, systemic lupus erythematosus, polyarteritis nodosa, and dermatomyositis. Occlusions of the palmar arches or digital arteries are common (Fig. 91.13).

Buerger disease (thromboangiitis obliterans) was initially described in male patients of Mediterranean origin who presented with digital gangrene but no occlusion of the larger arteries. Contemporary practice recognizes that men and women of many ethnic backgrounds can be affected. A persistent characteristic is a strong association with heavy smoking of a particularly addictive nature. The diagnosis of Buerger disease is based on histologic evidence of the involvement of both arteries and veins. Venous involvement can be manifested clinically as migrating phlebitis. Characteristic arteriographic findings include occlusion of the small arteries of the digits and the presence of abundant collaterals. The typical corkscrew appearance of the collaterals and lack of the large-vessel plaques characteristic of atherosclerosis are strongly suggestive. Like the symptomatic hand, the asymptomatic hand may demonstrate digital artery occlusions.

Polycythemia vera, cryoglobulinemia, and the presence of cold agglutinins are common blood dyscrasias associated with occlusion of the arteries of the hand. Occlusion of the small arteries is generally thought to be caused by local thrombosis or embolism. Specific immunologic and blood tests help to establish the diagnosis.

Iatrogenic injuries to the radial and brachial arteries have become more common because of the increasing use of diagnostic and therapeutic catheterization. These can be particularly troublesome when an incomplete palmar arch is not recognized before placement of a catheter in the radial artery. Gangrene or severe ischemia can result from the injury.

FIGURE 91.13. Arteriogram of a patient with scleroderma and digital gangrene. Extensive small-artery occlusion involves the palmar arch and digital arteries.

Vibration syndrome, characterized by blanching and numbness of the hands after the use of pneumatic drills, is a well-recognized clinical entity causing hand ischemia. The so-called vibratory white finger is a form of occupational trauma. Repetitive trauma to the digital arteries that initially causes spasm but ultimately causes thrombosis and permanent occlusion is believed to be the primary factor responsible for ischemic symptoms.

Hypothenar hammer syndrome is another form of occupational trauma, commonly seen in mechanics and carpenters. Injury follows repetitive use of the palm in activities that involve pounding, pushing, or twisting. The anatomic location of the ulnar artery at the area of hypothenar eminence makes it vulnerable to stress. When this area is repeatedly traumatized, ulnar artery occlusion (Fig. 91.14) or aneurysm formation can result (Fig. 91.15). Digital artery occlusion is a consequence of embolism from the injured artery.

Calciophylactic arteriopathy (heavily calcified arteries) in patients with diabetes or chronic renal failure can lead to gangrene or severe ischemia of the hand. The so-called azotemic arteriopathy (calciophylaxis) is characterized by calcification of the media of the digital arteries, which produces a “lead pipe” pattern on plain film.

TREATMENT

The type of reconstructive procedure depends on the underlying cause of ischemia, as well as the nature and location of the lesion. The results of bypass grafting in the upper extremity are similar to those of lower extremity revascularization—that is, proximal grafts fare better than distal grafts. In a recent report, the overall 5-year patency rate was 52.2% in 43 patients.²¹ The patency rate for anastomosis proximal to the

FIGURE 91.14. Occlusion of the ulnar artery over the hamate bone in a patient with hypothenar hammer syndrome.

brachial artery bifurcation was better than that for more distal placement (61.9% vs. 34.8%). Major amputation is not often required, even after graft occlusion, as it is in lower extremity surgery.

Cervical reconstruction via transposition is the surgical technique of choice for single proximal occlusive lesions involving the subclavian arteries. Multiple remote cervical bypasses or arch-based reconstruction should also be considered for patients with multiple supra-aortic trunk occlusive lesions. Arterial transpositions are completed through a short, transverse cervical incision above the clavicle. Not only is preservation of the vertebral artery critical, but also it is equally important to mobilize and preserve the valuable internal mammary artery when performing a subclavian transposition. The long-term patency rate for arterial transposition, when performed by surgeons with experience, is virtually 100%.^{9,22,23}

Occasionally, it is not feasible to do a straightforward arterial transposition so the use of a bypass from the ipsilateral carotid to the subclavian becomes necessary. Care must be taken to avoid injury to the phrenic nerve during this more lateral approach. The bypass is completed to the retroscalene portion of the subclavian artery, usually using prosthetic conduit, by performing sequential clamping and serial anastomoses.^{24,25}

Endoluminal treatment using balloon angioplasty and stenting of isolated innominate or subclavian artery disease is becoming more commonplace. Patients with atherosclerotic occlusive disease, as well as patients with inflammatory arteriopathies, have been treated with endovascular therapy. Endovascular recanalization is performed fluoroscopically via remote arterial access with wires, catheters, and angioplasty balloons that are directed to the target lesion. Therapy can be undertaken in antegrade fashion from the femoral artery or, in the case of innominate or subclavian lesions, a retrograde fashion, from the brachial artery. The routine use of metallic intravascular stents has become an adjunct to balloon angioplasty in the proximal segments of these vessels and covered stent grafts may have a role as well.²⁶ Stents should not be placed in the postvertebral subclavian artery because of the risk of stent compression. Endoluminal treatment of arteritis results in marginal success at best.

In general, no operation should be undertaken on patients with Takayasu arteritis while in an active phase signaled by the presence of the constitutional symptoms, acute inflammation, and an elevated erythrocyte sedimentation rate. Steroid therapy can treat the acute inflammatory process and may make surgical reconstruction much safer. The indications for vascular reconstruction in patients with Takayasu disease are the same as those for treating patients with atherosclerosis.

Arterial complications of thoracic outlet obstruction often require a bypass procedure. After resection of a subclavian artery aneurysm and removal of the cervical rib, the damaged subclavian artery is reconstructed with either venous or prosthetic conduit.²⁷

A bypass graft with autogenous vein (saphenous or cephalic) often relieves occlusion of the brachial artery and its major branches.²⁸ A short segmental occlusion of either the radial or ulnar artery may be treated by thrombectomy or endarterectomy with a vein patch. An aneurysm in the hand can be resected and continuity restored by end-to-end anastomosis or with an interposed lesser saphenous vein graft.

Distal lesions with occlusion at or distal to the palmar arch may not be amenable to direct surgical treatment. Conservative

FIGURE 91.15. Thrombosed ulnar aneurysm (in situ) (A) and pathologic specimen (B).

FIGURE 91.16. Bypass to the superficial palmar arch.

treatment with the use of a calcium blocker (e.g., nifedipine) may reduce the severity and frequency of attacks. A host of medications have been recommended.²⁹ Occasionally, a reasonable distal target for bypass is identified in the hand (Fig. 91.16). Microvascular reconstruction, with or without digital sympathectomy, may also be effective in particularly recalcitrant cases.

In all patients with upper extremity ischemia of any cause, cessation of smoking is important. Many of the constituents of tobacco smoke cause adverse vascular effects, particularly vasoconstriction, with particularly prominent effects in the upper extremity. Protective measures, such as avoiding exposure to cold temperatures and mechanical trauma, have beneficial effects when scrupulously applied.

The author would like to extend many thanks to James S.T. Yao, M.D., for his contributions to previous chapters upon which this one was based.

CHAPTER 92 ■ RENAL ARTERY OCCLUSIVE AND ANEURYSMAL DISEASE

GILBERT R. UPCHURCH, Jr., PETER K. HENKE, JOHN E. RECTENWALD, JONATHAN L. ELIASON, AND JAMES C. STANLEY

KEY POINTS

- 1 Renal artery disease is recognized with increasing frequency with the advent of less invasive imaging modalities.
- 2 Renovascular hypertension secondary to renal artery occlusive disease is the most common form of surgically correctable hypertension, and is more common in adult patients with more severe diastolic blood pressure elevations; as many as 5% of such patients are found to have a renovascular cause of their hypertension.
- 3 Arteriosclerotic renal artery occlusive disease accounts for about 95% of reported cases of renovascular hypertension.
- 4 Medial fibroplasia is the most commonly diagnosed nonarteriosclerotic renal artery disease, accounting for 85% of dysplastic lesions.
- 5 Treatment of renovascular hypertension is in evolution.
- 6 Aneurysms of the renal artery are unusual and poorly understood vascular lesions and should generally be repaired in woman of childbearing age, when their diameter exceeds 1.5 cm, or when they are associated with hypertension.

- 1 Renal artery diseases is recognized with increasing frequency with the advent of less invasive imaging modalities. The clinical importance of renal artery occlusive disease, be it due to arteriosclerosis, fibrodysplasia, or a developmental anomaly, warrants individual discussion. Similarly, renal artery aneurysms, be they true aneurysms or dissections, also warrant separate consideration.

The consequence of renal artery occlusive disease causing elevated blood pressure is well recognized and may be one of the most untreated vascular diseases in contemporary times. While true renal artery aneurysms and dissecting aneurysms are relatively uncommon, evidence suggests that they too may contribute to a hypertensive state in certain patients. The role of renal artery occlusive and aneurysmal disease as a cause of diminished renal function is less well defined.

RENAL ARTERY OCCLUSIVE DISEASE

- 2 Renovascular hypertension secondary to renal artery occlusive disease is the most common form of surgically correctable hypertension. Systemic blood pressure elevations in these patients follow reductions in renal perfusion with activation of the renin-angiotensin system. This physiologic response tends to restore the renal artery perfusion pressures toward normal, although it does so in a pathologic manner by producing hypertension in the systemic circulation.

Pathophysiology of Renovascular Hypertension

The physiologic basis of renovascular hypertension is well defined. This form of hypertension was first recognized more than 60 years ago by Goldblatt et al.,¹ who produced sustained hypertension in a canine model after gradual reductions in renal artery blood flow using an externally controlled vascular clamp. Subsequent studies have discounted the importance of

renal ischemia per se as the cause of renovascular hypertension, with other hemodynamic signals appearing essential in increasing renin release, the most obvious being a decrease in mean renal artery perfusion pressure. A stenosis causing an 80% reduction in renal artery cross-sectional area (a so-called critical stenosis) induces a pressure gradient sufficient to cause increased renin release from the kidney. Renin and its effects on angiotensin and aldosterone account for the elevated blood pressure of renovascular hypertension (Fig. 92.1).

Renin is produced by the juxtaglomerular apparatus of the kidney. This anatomic area consists of a variety of cells, including *myoepitheloid cells* or *granular cells*, located on the wall of the afferent arterioles; the *macula densa*, which is composed of specialized tubular epithelial cells in the glomerular hilus at the transition of the loop of Henle to the distal convoluted tubule; and *lacis cells*, located in the region of the efferent glomerular arteriole and the macula densa. Lacis cells are intimately associated with the glomerulus and are anatomically similar to mesangial cells. The interrelations between the macula densa, glomerular arteriole vasomotion, and renal tubular function are important in understanding renin kinetics.

Regulation of renin production and its release from the kidney at the cellular and molecular level is complex. Renal baroreceptors, acting as stretch receptors, affect the release of renin from juxtaglomerular cells. Activation of these receptors appears to involve the calcium ion, with increasing evidence that renin release and intracellular levels of calcium are inversely related. Alternatively, renin release can occur with changes in pressure at the afferent renal arteriole level, as well as with changes in renal interstitial volume and pressure.

Renin is a proteolytic enzyme, active at a neutral pH on its only known substrate, angiotensinogen. Renin is a single-chain polypeptide with a molecular weight of about 38 kD.² It is stored as granules within the juxtaglomerular cells and, in some instances, as granules within the arteriolar wall. Renin has a half-life of 20 to 30 minutes. Under usual circumstances of normal sodium balance, the sum of renin activity measured in both renal veins is about 48% greater than that in the infrarenal vena cava or peripheral arterial and venous circulations.³ The renin levels in the peripheral circulation appear to

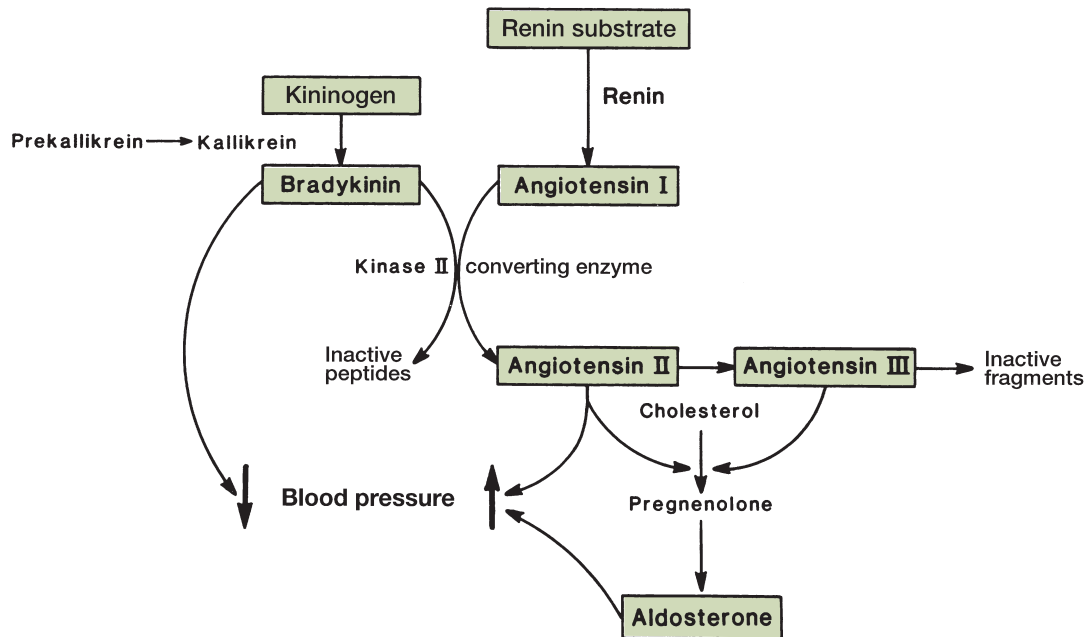

FIGURE 92.1. Renin-angiotensin system interrelation with aldosterone and bradykinin in regulation of blood pressure. (Adapted from Stanley JC, Graham LM, Whitehouse WM Jr. Renovascular hypertension. In: Miller TA, Rowland BJ, eds. *Physiologic Basis of Modern Surgical Care*. St. Louis, MO: CV Mosby; 1988:734.)

be in a steady state because of this relatively constant 48% contribution of renin from the kidneys. The liver is the primary site for removal and clearance of renin.⁴ Extrarenal renin or reninlike enzymes (isorenins) exist in the submaxillary salivary gland, uterus, placenta, and brain, but there is no evidence that these substances are functionally important in elevating blood pressure.

The biochemistry of the renin-angiotensin system has been well defined (Fig. 92.2). The primary, if not sole, function of renin is the hydrolysis of renin substrate (a circulating peptide known as *angiotensinogen*) to form angiotensin I. Angiotensinogen is an α_2 -globulin with a molecular weight of 60 kD. It is produced in the liver. Expression of the angiotensinogen gene is subject to a variety of physiologic and pathophysiologic stimuli, including steroid hormones, angiotensin II, salt loading, and various drugs. Angiotensinogen itself has no vasoactive properties.

Angiotensin I, a decapeptide produced by the renin-angiotensin substrate reaction, has little vasoactivity. It does exert an effect on the adrenal medulla, the sympathetic and central nervous systems, and the renal arterioles. Angiotensin II is formed

when two C-terminal peptides are cleaved from angiotensin I by the carboxypeptidase angiotensin-converting enzyme (ACE). Angiotensin II, an octapeptide, represents the vasoconstrictive element of renovascular hypertension. Although angiotensin II stimulates liver production of renin substrate, in normal subjects, it provides a continuous negative feedback on renal release of renin.⁵ Angiotensin II has a half-life of about 4 minutes. Angiotensin III, a heptapeptide, is produced with the aminopeptidase cleavage of angiotensin II to I-des-aspartyl-angiotensin II. Angiotensin III is known to inhibit angiotensin II, but its most relevant effect is to increase aldosterone synthesis. Nevertheless, angiotensin III has little biologic activity of physiologic importance.

Aldosterone is secreted from the zona glomerulosa of the adrenal cortex and represents the volume element of renovascular hypertension. The biosynthesis of this mineralocorticoid includes cleavage of a side chain of cholesterol to form pregnenolone. This step is facilitated by both angiotensin II and III. Aldosterone increases renal conservation of sodium and water, with a subsequent extracellular fluid volume expansion and an eventual increase in blood pressure.

ACE (dipeptidyl carboxypeptidase) is a zinc metallopeptidase responsible for producing angiotensin II from angiotensin I by removing C-terminal peptides from angiotensin I. ACE has its highest concentration in the endothelium of the pulmonary circulation. Conversion of angiotensin I to angiotensin II, at physiologic concentrations, occurs in a single passage through the lungs.⁶ ACE has been found at lower levels in the blood and kidney as well as in other vascular beds. ACE is also important in the metabolism of the vasodepressor bradykinin. At least two enzymes appear to inactivate bradykinin. The first, kinase I, acts by cleaving the carboxy-terminal arginine of bradykinin. The second, kinase II, acts by cleaving the carboxy-terminal dipeptide group Phe-Arg. Kinase II and ACE appear to be similar in that they have nearly identical substrate specificities, cofactor requirements, and antigenic specificities.⁷

The actions of angiotensin on cardiac activity, vascular smooth muscle reactivity, and sodium and water metabolism contribute to increased arterial pressure (Fig. 92.3). The most important consequence of renal artery occlusive disease is the production of angiotensin II, which is one of the most potent

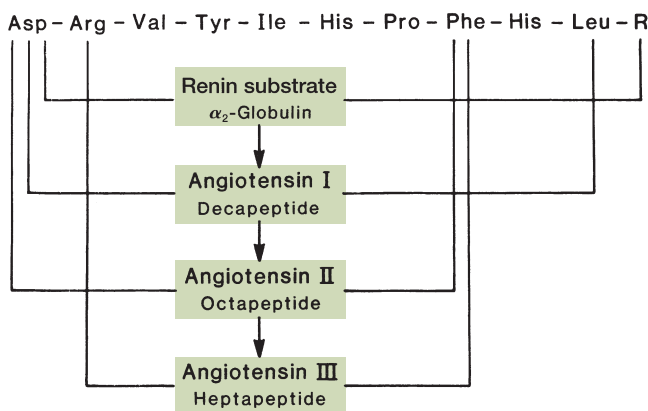

FIGURE 92.2. Biochemical composition of renin substrate and the angiotensins. (Adapted from Stanley JC, Graham LM. Renovascular hypertension. In: Miller TA, ed. *Physiologic Basis of Modern Surgical Care*, 2nd ed. St. Louis, MO: Quality Medical Publishing; 1998:918.)

pressor substances known. Angiotensin II acts directly on arteriolar smooth muscle of nearly all vascular beds; the splanchnic, renal, and cutaneous circulations are most sensitive to its effects. There is a general acceptance of the central importance of angiotensin in the generation of renovascular hypertension.

Hemodynamic responses to an activated renin-angiotensin system depend on the rate of alterations in renal blood flow as well as on whether one or both kidneys are affected. Acute reductions in renal blood flow result in rapid increases in plasma renin and blood pressure. In the case of unilateral renovascular disease with a normal opposite kidney, the hypertension is characterized by renin hypersecretion from the affected kidney and suppression of renin production in the contralateral kidney.^{8,9} Sodium retention within the affected kidney is counterbalanced by continuous sodium excretion from the normal contralateral kidney, resulting in a relative intravascular volume depletion. This vasoconstrictive form of hypertension is angiotensin II dependent and responds to ACE inhibitors.

Pathophysiologic alterations accompanying bilateral renovascular disease, or unilateral disease of a solitary kidney, relate to changes other than vasoconstriction. Angiotensin II causes sodium retention, diminutions in glomerular filtration, stimulation of aldosterone production, and stimulation of norepinephrine release from the adrenergic nervous system. In chronic bilateral or unilateral renovascular hypertension in patients with only one kidney, sodium retention accounts for late reductions in renin secretion, although it is possible that absolute renin activity is abnormally high with regard to the existing sodium balance. Blood pressure elevations do not appear as dependent on the renin-angiotensin system in sodium-replete chronic renovascular hypertension. In this setting, ACE inhibitors are more effective in reducing elevated blood pressures with sodium depletion.¹⁰

Pathology of Renal Artery Occlusive Disease

Different macrovascular occlusive diseases affect the renal arterial circulation.^{11,12} The most common are arteriosclerosis and arterial fibrodysplasia. Developmental renal artery narrowings are a rare cause of renovascular hypertension. Although uncommon, renal artery emboli and traumatic

occlusions are occasionally associated with acute renin-mediated hypertension.

3 Arteriosclerosis. Renal artery occlusive disease due to arteriosclerosis accounts for 95% of reported cases of renovascular hypertension (Fig. 92.4). This type of renovascular hypertension may be even more common because many earlier reported experiences were surgical series that excluded older patients who were not open operative candidates and thus not evaluated for this disease. A recent study using a large administrative database showed that the diagnosis of renovascular hypertension and renal artery atherosclerosis in the United States has increased 46% over the years 1988 to 2001.¹³ Arteriosclerotic renovascular disease most commonly presents during the sixth decade of life. Men are affected twice as often as women. Although some degree of arteriosclerotic renal artery stenotic disease affects nearly half of the elderly population, it is not always associated with elevated blood pressures. Many of these patients exhibit occlusive disease of the coronary, cerebral, mesenteric, or extremity circulation.^{14–16} This is particularly the case in black patients, who exhibit more severe extrarenal arteriosclerotic vascular disease.¹⁷

Arteriosclerotic renal artery occlusive disease characteristically affects the proximal third of the vessel in the form of eccentric or concentric stenosis. In nearly 80% of cases, these lesions represent spillover of diffuse aortic atherosclerosis. Arteriosclerotic renal artery lesions are bilateral in three quarters of patients. When unilateral, these lesions affect the right and left renal arteries with equal frequency, although the left renal artery often appears more severely diseased. Intimal and medial accumulations of cholesterol-laden foam cells and fibrous tissue are typical of these lesions. Necrosis, hemorrhage, calcification, and luminal thrombus are characteristic of complicated atherosclerotic plaques associated with more advanced disease.

Arterial Fibrodysplasia. The second most common type of renal artery disease is arteriofibrodysplasia, accounting for about 5% of reported cases of renovascular hypertension.^{11,12} Dysplastic renal artery stenosis represents a heterogeneous group of lesions. They are classified by the specific pathologic process and vessel wall region most affected. Included among

FIGURE 92.4. Renal artery arteriosclerosis. **A:** Intrinsic focal lesion of proximal renal artery. **B:** Severe aortic spillover disease affecting renal artery orifice and entire abdominal aorta. **C:** Complicated renal artery plaque exhibiting collections of cholesterol, extensive fibrosis, and calcification (hematoxylin–eosin, $\times 60$). (A and C reproduced with permission from Stanley JC. Morphologic, histopathologic and clinical characteristics of renovascular fibrodysplasia and arteriosclerosis. In: Bergan JJ, Yao JST, eds. *Surgery of the Aorta and Its Body Branches*. New York: Grune & Stratton; 1979:355; B reproduced with permission from Stanley JC, Graham LM, Whitehouse WM Jr. Renovascular hypertension. In: Miller TA, Rowland BJ, eds. *Physiologic Basis of Modern Surgical Care*. St. Louis, MO: CV Mosby; 1988:734.)

these lesions are intimal fibroplasia, medial fibroplasia, and perimedial dysplasia.¹⁸ The last two entities appear to be a continuum of the same disease process. Each category has certain characteristic features deserving individual comment.

Intimal fibroplasia accounts for about 5% of all dysplastic renal artery stenosis (Fig. 92.5). These lesions occur in children and young adults more often than in the elderly, and they affect both genders equally. The cause of primary intimal fibroplasia is unknown but may be related to persistent embryonic myointimal cushions. Secondary intimal fibroplasia has been attributed to flow disturbances, blunt abdominal trauma, and the sequela of an earlier arteritis, such as occurs with rubella. Progression of intimal fibroplasia may cause turbulent blood flow and a rapidly accelerated fibroproliferative response that compromises the arterial lumen.

Intimal fibroplasia usually presents as a smooth, focal stenosis of the distal main renal artery. In some patients, these lesions produce long, tubular stenosis, and in rare cases, they present as webs affecting segmental arteries. Proximal ostial lesions most often represent the secondary form of this disease, associated with abdominal aortic hypoplasia and coarctation. Subendothelial accumulations of irregularly arranged mesenchymal cells surrounded by loose fibrous connective tissue are typical of all intimal fibrodysplastic lesions. The internal elastic lamina is usually intact, but partial fragmentation may occur. Medial and adventitial structures are normal in primary intimal fibrodysplasia.

4 Medial fibroplasia is the most commonly diagnosed dysplastic renal artery disease, accounting for 85% of these lesions (Fig. 92.6). Medial fibroplasia is invariably found in women, with cases in men being anecdotal. The clinical presentation of this disease is most common between 25 and 45 years of age.

Medial fibroplasia appears to be a systemic arteriopathy, with the internal carotid arteries representing the extrarenal vessels most often affected. The cause of medial fibroplasia remains poorly understood but appears to be associated with modification of smooth muscle to myofibroblasts caused by estrogenic stimuli during the reproductive years, unusual traction forces on affected vessels, and mural ischemia from impairment of vasa vasorum blood flow.¹⁸ The physical forces contributing to medial fibroplasia may be attributed to ptotic kidneys with stretching of the renal arteries (Fig. 92.7). The fact that renal ptosis occurs more often in women than in men may explain the almost unique involvement of the renal artery with medial fibroplasia in women.

Morphologic appearances of medial dysplasia range from a solitary stenosis to multiple constrictions with intervening mural dilations affecting the middle and distal main renal artery. The latter are responsible for this lesion's classic string-of-beads appearance. Actual macrovascular aneurysms occurring at branchings affect a little more than 10% of patients with arterial fibrodysplasia. Stenotic disease of segmental branches occurs in about 25% of cases. Bilateral disease affects nearly 60% of patients and is usually most severe on the right. Unilateral lesions affect the left and right renal arteries in 10% and 30% of cases, respectively. Progression of disease occurs in about 20% of premenopausal women.

Perimedial dysplasia accounts for nearly 10% of dysplastic renal artery stenotic disease (Fig. 92.8). These lesions invariably occur in women, usually between the ages of 30 and 50 years. Perimedial dysplasia is bilateral in 20% of patients and appears to be more progressive than medial fibrodysplasia. Perimedial dysplasia is characterized by solitary or multiple

FIGURE 92.5. Intimal fibroplasia. **A:** Focal stenosis of main renal artery midportion. **B:** Subendothelial mesenchymal cells within a loose fibrous connective tissue matrix are noted above an intact internal elastic lamina, normal media, and normal adventitial tissues (hematoxylin–eosin, $\times 120$). (A reproduced with permission from Stanley JC, Fry WJ. Renovascular hypertension secondary to arterial fibrodysplasia in adults: criteria for operation and results of surgical therapy. *Arch Surg* 1975;110:922–928; B reproduced with permission from Stanley JC. Morphologic, histopathologic and clinical characteristics of renovascular fibrodysplasia and arteriosclerosis. In: Bergan JJ, Yao JST, eds. *Surgery of the Aorta and Its Body Branches*. New York: Grune & Stratton; 1979:355.)

constrictions, without intervening dilations. Most stenoses involve the distal main renal artery, without segmental branch involvement. Certain histologic features are common to both perimedial dysplasia and medial fibroplasia, and they may represent different manifestations of the same pathologic entity. Although unusual accumulations of elastic tissue in inner adventitial regions is the most prominent abnormality in peri-

medial dysplasia, increases in medial ground substances may also accompany this type of dysplastic disease.¹⁸

Developmental Renal Artery Disease. Narrowings of the renal artery occurring during fetal growth are a rare cause of renovascular hypertension. They are often associated with both abdominal aortic coarctation and splanchnic

FIGURE 92.6. Medial fibroplasia. **A:** Serial stenoses alternating with mural aneurysms, producing a string-of-beads appearance in the midportion and distal main renal artery. **B:** Diffuse form of medial fibroplasia exhibiting regions of excess fibroproliferation with intervening area of medial thinning (Masson stain, $\times 60$, longitudinal section). (Reproduced with permission from Stanley JC. Morphologic, histopathologic and clinical characteristics of renovascular fibrodysplasia and arteriosclerosis. In: Bergan JJ, Yao JST, eds. *Surgery of the Aorta and Its Body Branches*. New York: Grune & Stratton; 1979:355.)

FIGURE 92.7. Medial fibrodysplasia manifested as irregular narrowings to ptotic kidneys affecting the midportion of the main renal arteries, which appear stretched during upright aortography. (Reproduced with permission from Stanley JC, Wakefield TW. Arterial fibrodysplasia. In: Rutherford RB, ed. *Vascular Surgery*, 5th ed. Philadelphia, PA: WB Saunders; 2000:387.)

arterial stenoses^{19–24} (Fig. 92.9). These lesions are encountered most often in children and young adults. About 40% of children with renovascular hypertension are thought to have developmental renal artery stenosis. Similarly, nearly 20% of adults with primary intimal fibroplastic renal artery disease have stenoses that can be attributed to developmental defects. Boys slightly outnumbered girls. These stenotic lesions represent true hypoplasia of the renal artery, exhibiting an external hourglass appearance. Developmental lesions usually occur at the aortic origin of the artery. Sparse medial tissue, intimal fibroplasia, fragmentation and duplication of the internal elastic lamina, and disproportionate excesses in adventitial elastic tissue are the most common histologic abnormalities in these diminutive vessels.^{20,21,23}

Developmental renal artery narrowings may be attributed to certain embryonic events occurring as the two fetal dorsal aortas fuse and all but one of their metanephric branches to the kidney regress. Abnormal transition of mesenchymal to medial smooth muscle at that time, or later impairment of its growth, can cause both aortic and renovascular anomalies. Vessels to the mesonephros within mesenchymal tissue around the two dorsal aortas are replaced during fetal growth by a more cephalic group of vessels to the metanephros. That a solitary artery to each kidney evolves from these arteries in 75% of people has been attributed to its obligate hemodynamic advantage over adjacent channels. Flow changes in the region where single central renal arteries usually arise may afford coexisting polar arteries hemodynamic advantages that ensure their persistence. Supporting such a hypothesis concerning the cause of developmental lesions is the fact that multiple stenotic renal arteries exist in more than half of those patients with central abdominal aortic coarctation or hypoplasia.

FIGURE 92.8. Perimedial dysplasia. **A:** Multiple stenoses without mural aneurysms in the midportion of the renal artery are characteristic of these lesions. **B:** These lesions are due to excessive accumulations of elastic tissue at the medial-adventitial junction (Verhoeff stain, $\times 120$). (Reproduced with permission from Stanley JC. Morphologic, histopathologic and clinical characteristics of renovascular fibrodysplasia and arteriosclerosis. In: Bergan JJ, Yao JST, eds. *Surgery of the Aorta and Its Body Branches*. New York: Grune & Stratton; 1979:355.)

FIGURE 92.9. Developmental renal artery stenoses. **A:** Proximal vessel stenosis in a patient with neurofibromatosis and infrarenal aortic hypoplasia. **B:** Fragmentation and duplication of the internal elastic lamina and deficient medial tissues characterize these lesions. Intimal fibroplasia encroaches on the vessel lumen, which is less than 1 mm in diameter. Adventitial elastic tissues appear excessive (Movat stain, $\times 100$). (A reproduced with permission from Stanley JC, Fry WJ. Pediatric renal artery occlusive disease and renovascular hypertension: etiology, diagnosis, and operative treatment. Developmental occlusive disease of the abdominal aorta and the splanchnic and renal arteries. *Arch Surg* 1981;116:669–676; B reproduced with permission from Stanley JC, Graham LM, Whitehouse WM Jr, et al. Developmental occlusive disease of the abdominal aorta and the splanchnic and renal arteries. *Am J Surg* 1981;142:190–196.)

Clinical Features of Renovascular Hypertension

The frequency of renovascular hypertension among adult patients who have diastolic blood pressures higher than 100 mm Hg is about 2%. It is much more common in patients with more severe diastolic blood pressure elevations; as many as 5% of such patients are found to have a renovascular cause of their hypertension. It is the second most common cause of hypertension in childhood, being outnumbered only by thoracic isthmic aortic coarctation.

Findings suggestive of renovascular hypertension include upper abdominal bruits during both systole and diastole, initial diastolic blood pressures greater than 115 mm Hg, a sudden worsening of mild to moderate essential hypertension, development of hypertension during childhood, or rapid onset of high blood pressure after the age of 50 years. Hypertension resistant to drug therapy and malignant hypertension are also more likely to be associated with this form of secondary hypertension. Similarly, patients who exhibit deterioration in renal function while receiving multiple antihypertensive drugs, especially ACE inhibitors, may have underlying renal artery stenotic disease. The costs and errors incumbent to indiscriminate evaluations for this form of hypertension that lead to unnecessary interventions are prohibitive. A useful decision algorithm in contemporary practice is based on the presenting degree of hypertension and presence or absence of clinical and laboratory evidence suggesting the existence of renovascular hypertension (Algorithm 92.1).

Diagnosis of Renal Artery Occlusive Disease and Secondary Hypertension

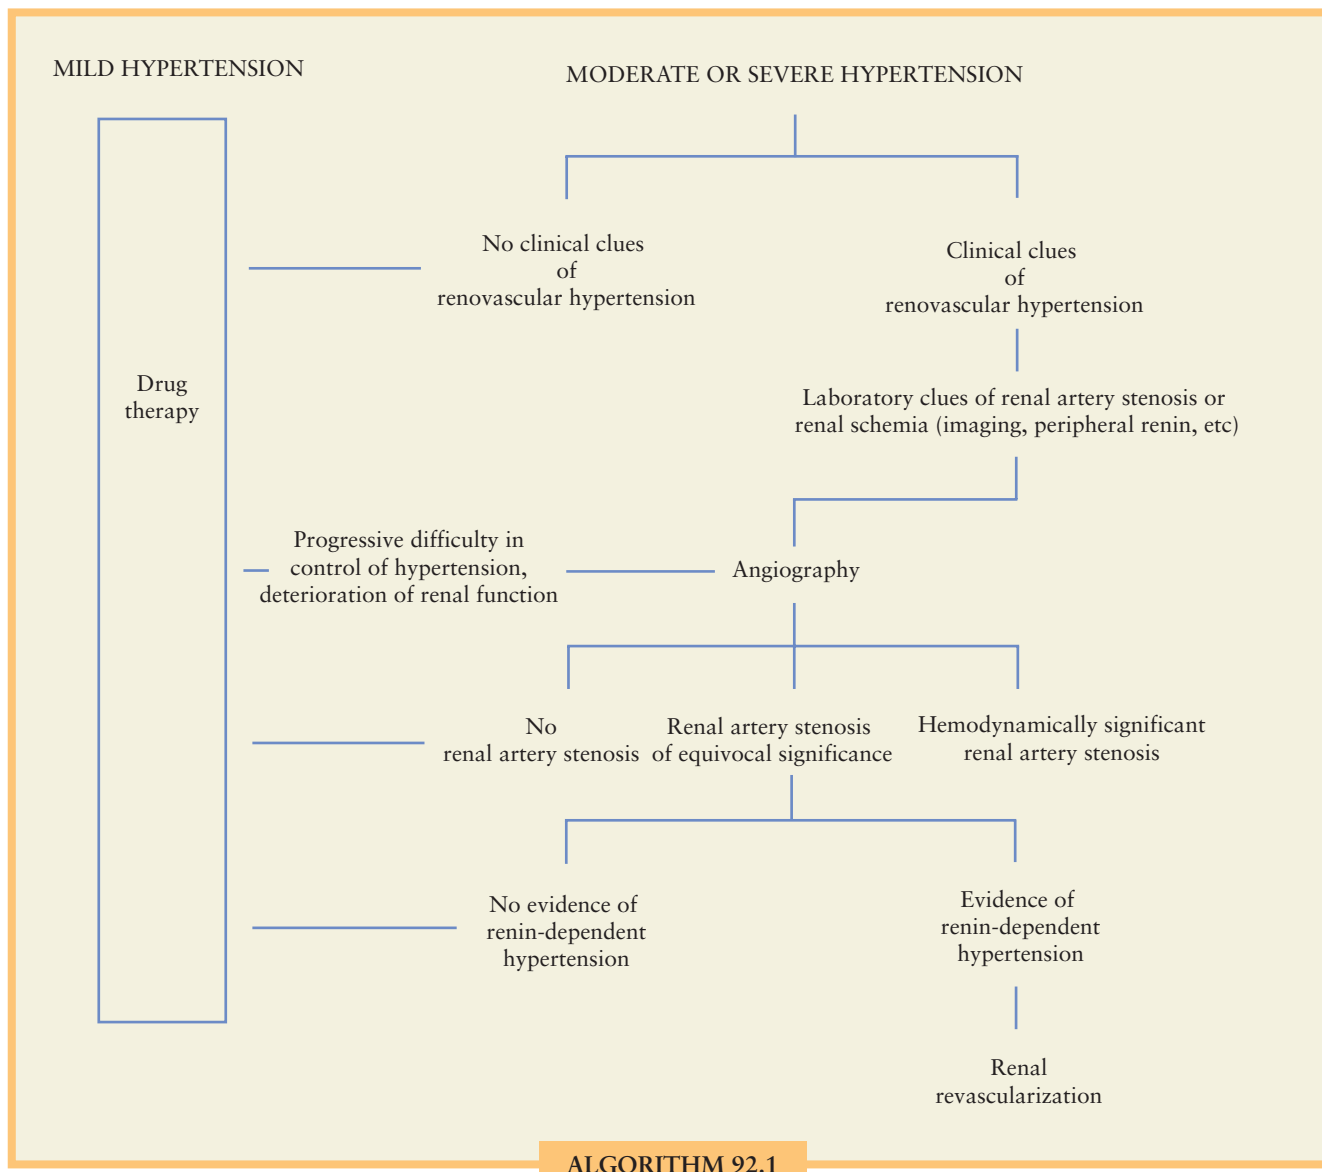

Most diagnostic and prognostic tests for renovascular hypertension assess either the anatomic stenosis or derangements of

renal function attributed to the stenosis. The usefulness and limitations of these tests become relevant in the selection of patients for open surgical or endovascular interventions.

Deep abdominal renal artery ultrasonography may identify hemodynamically significant renal artery narrowings by imaging the renal arteries and characterizing flow velocity patterns through these vessels^{25,26} (Fig. 92.10). Ultrasonography is a reasonable initial screening test. Existence of a stenosis appears established when peak systolic velocities are in the range of 180 to 200 cm/s and the ratio of these velocities to those in the aorta approaches 3.5. Unfortunately, ultrasonography does not discriminate among renal artery stenosis exceeding 60% cross-sectional narrowing. Failure to identify a main renal artery in the absence of any parenchymal flow signal suggests main renal artery occlusion. An occluded accessory or segmental renal artery, however, may not be recognized and, thus, contributes to this technology's false-negative assessments.

Computed tomographic arteriography (CTA) is another frequently used means of assessing coexistent renal artery disease (Fig. 92.11). It allows computer-generated visualization of the vessels from many different angles not possible with conventional biplanar arteriography. However, CTA carries the risk of contrast-induced nephrotoxicity.

Arteriography was central to past evaluations of patients suspected of having hypertension. Oblique aortography and multiple-plane selective renal arteriography have improved the recognition of the morphologic character and extent of renal artery stenosis in this disease entity. Collateral vessels circumventing a renal artery stenosis are evidence of the lesion's hemodynamic importance. A pressure gradient approaching 10 mm Hg is necessary for collateral vessel development, and the same degree of pressure change is associated with activation of the renin system. Thus, the functional importance of an otherwise benign-appearing stenosis is established when collateral vessels are evident (Fig. 92.12). *Intra-arterial digital subtraction angiography* allows use of smaller quantities of

ALGORITHM 92.1

iodinated contrast agents compared with conventional arteriography, and it lessens the potential of contrast-induced nephrotoxicity. This is of particular relevance in patients with compromised renal function. The use of carbon dioxide in the latter circumstances is also appealing, but may not always provide sufficient anatomic detail for clinical decision making in patients with more distal segmental arterial disease.²⁷

Magnetic resonance angiography (MRA), especially with breath-hold techniques and gadolinium enhancement, provides reasonable images of diseased renal arteries.^{28,29} A normal study usually confirms absence of disease, but because of phase dropout with vessel tortuosity, a study may appear abnormal in a patient having a relatively minor stenotic disease. Nevertheless, MRA's noninvasiveness and lack of nephrotoxicity make it an attractive diagnostic test. The documentation of nephrogenic dermatofibrosis following the administration of gadolinium in patients with renal insufficiency has lessened the enthusiasm for the use of MRA in studying patients suspected of having renal artery stenosis.³⁰

The use of physiologic tests to confirm the importance of anatomic narrowings is performed less frequently for a number of reasons, including the significant expense of the preparation

required prior to these studies, as well as lack of sensitivity for certain tests.

Renin activity comparing peripheral and renal venous blood, in the past, was a recognized means of detecting functionally important renal artery disease. Today, renin assessments are undertaken in the rare patient with complex but equivocal disease, when the risk of an intervention demands a confirmed diagnosis. The **renal vein renin ratio (RVRR)** is calculated by dividing the renin activity in venous blood from the affected kidney by that from the contralateral kidney. An RVRR of greater than 1.48 is indicative of functionally important renovascular stenotic disease.^{8,9} Because this test compares one kidney to another, it may not be useful in patients with bilateral disease if both kidneys exhibit elevated but equal degrees of excessive renin secretion. The **renal:systemic renin index (RSRI)** avoids this problem, and is calculated by subtracting systemic renin activity from individual renal vein renin activity and dividing the remainder by systemic renin activity.⁸ It is an expression of individual kidney renin release. In nonrenovascular essential hypertensive patients, renal vein renin activity from each kidney is usually 24% higher than systemic activity.^{3,9} Thus, the total of both kidneys' activity is usually

FIGURE 92.10. Renal artery ultrasonography depicting velocity measurements (A) used to calculate the aortic-to-renal artery ratio, percent stenosis by image with grayscale and color images (B), and resistive index.

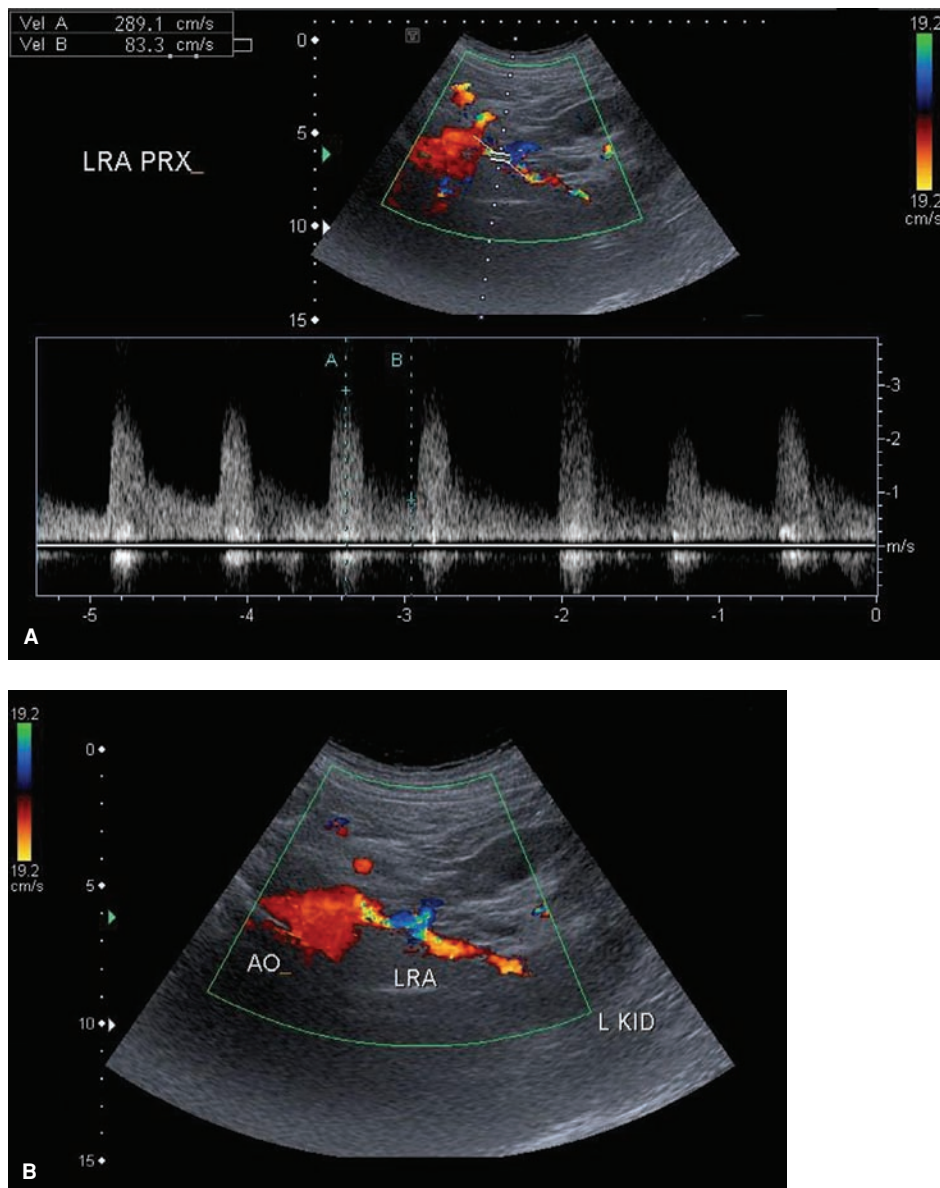

FIGURE 92.11. Computed tomographic arteriography of renal artery affected with fibromuscular dysplasia (arrow), exhibiting typical string-of-beads characteristic of medial fibroplasia.

48% higher than systemic activity and represents a steady state of normal renal renin release. The usefulness of ischemic kidney renin hypersecretion (RSRI more than 0.48) and contralateral kidney renin suppression (RSRI less than 0.24, approaching 0) as a means of discriminating between expected cured and improved operative outcomes has been well established.^{8,31}

Hypertensive urography is not a good diagnostic test for renovascular hypertension because of its limited sensitivity.³² Bilateral or segmental disease may interfere with the recognition of gross differences in contrast excretion between the two kidneys. In a large series of patients with proven renovascular hypertension, urograms were abnormal in only 27% of children with developmental disease, 48% of adults with arterial fibrodysplastic disease, and 72% of adults with atherosclerotic lesions.³³ Thus, use of hypertensive urography as a diagnostic or prognostic test for renovascular hypertension appears unjustified.

Isotopic renography allows both renal imaging and analysis of the washout curve of a number of radioactive tracers. A number of compounds have been used for these studies, including ^{99m}technetium-diethylenetriamine pentaacetic acid, iodine 123-orthiodohippurate or iodine 131-orthiodohippurate, ^{99m}technetium mercaptoacetyltriglycine, ^{99m}technetium-

FIGURE 92.12. Arteriogram of a benign-appearing stenosis (*black arrow*) associated with a large collateral vessel (*white arrow*) circumventing the lesion, defining hemodynamic significance of the stenosis and implicating its functional importance. (Reproduced with permission from Stanley JC, Graham LM, Whitehouse WM Jr. Limitations and errors of diagnostic and prognostic investigations in renovascular hypertension. In: Bernhard VM, Towne JM, eds. *Complications in Vascular Surgery*. Orlando, FL: Grune & Stratton; 1984:213.)

dimercaptosuccinic acid, and ^{99m}Tc glucoheptonate. These studies provide an assessment of renal blood flow as well as excretory function. Unfortunately, different states of hydration and intrarenal vascular resistance often contribute to flow abnormalities and false-positive studies in nonrenovascular hypertensives. The specificity and sensitivity of these studies are both about 75%. Administration of ACE inhibitors improves the sensitivity and specificity by blocking the compensatory change in glomerular filtration, causing it to fall in the affected kidney. The widespread use of this modified technology has not occurred, although some view ACE inhibitor-modified studies to be of greater value.³⁴ Renal perfusion/excretion ratios and more sophisticated computer analyses offer a potential means of increasing the predictive value of radionuclide screening for renovascular hypertension.

Treatment of Renal Artery Occlusive Disease

- 5** Treatment of renovascular hypertension is in evolution. Therapeutic results in the management of renovascular hypertension relate to both the proper selection of patients having clinically relevant renal artery disease as well as the execution of an appropriate intervention. Treatment options include drug therapy, percutaneous transluminal angioplasty (PTA) with or without stent placement, transcatheter renal ablation, arterial reconstructive surgery, and nephrectomy.

Drug Therapy of Renal Artery Occlusive Disease. Anti-hypertensive drugs are often used in the initial management of patients with renovascular hypertension. Beta-blocking agents, such as propranolol and atenolol, are commonly used as first-line therapy. Refractory hypertension, especially that caused by bilateral disease or unilateral lesions in patients with a solitary kidney or contralateral parenchymal disease, may respond to the addition of a thiazide diuretic, although with impaired renal function, the use of a loop diuretic, such as furosemide, is more effective.

ACE inhibitors, such as captopril and enalapril, have proved to be relatively effective drugs in treating renovascular hypertension. Unfortunately, ACE inhibitors may have a deleterious effect on renal function by preferentially dilating the glomerular efferent arterioles, critically decreasing the intraglomerular blood pressure, and reducing glomerular filtration. Certainly, ACE inhibitors must be used cautiously in renovascular hypertensive patients who have bilateral disease or a solitary kidney. Monitoring of renal function is mandatory after initiating treatment with ACE inhibitors. Use of angiotensin receptor blockers has not been well defined in this subgroup of hypertensive patients. Similarly, direct renin inhibitors, which have been shown to stabilize atherosclerotic plaque progression, have not been examined in the treatment of renovascular hypertension.³⁵

Because stenotic disease of the renal artery often progresses with concomitant loss of renal mass and function, a definitive means of restoring normal renal blood flow may be more logical therapy than drug treatment, once a diagnosis of renovascular hypertension has been established.

Endovascular Therapy of Renal Artery Occlusive Disease. In 1978, Grüntzig was the first to report the use of PTA in the management of renovascular hypertension.³⁶ The less invasive nature of renal artery PTA offers certain advantages over operative intervention and this therapy is now used widely. Most renal artery stenoses can be traversed with a guide wire and subsequently dilated with or without a stent, with minimal morbidity and mortality (Fig. 92.13). To justify

PTA, the clinical significance of the renal artery stenosis should be documented prior to initiating endovascular therapy. In addition, it is important that the patient should have adequate renal cortical reserve to recover renal function postintervention. A recent study has confirmed an explosive increase of endovascular therapy compared with open surgical therapy.¹³ In many regards this therapy has been applied to what some considered functionally irrelevant renal artery narrowings, with resultant benefits being less than would occur with more carefully selected individuals for such interventions.

Arterial Fibrodysplasia. Patients with renal artery fibrodysplasia benefit the most and incur the fewest complications following renal PTA, compared to those with other types of renal artery disease. Medial dysplastic stenoses are most amenable to PTA, and this is most often the primary therapy for lesions limited to the main renal artery. Excellent early technical and clinical results usually follow renal artery PTA in these patients.^{37–42} Similarly, these patients have experienced excellent long-term clinical results, with primary patency rates of around 85% (Table 92.1).⁴³

Developmental Disease. In contrast, renal artery ostial stenoses in pediatric patients associated with developmental aortic anomalies represent true hypoplastic vessels that are less

likely to be successfully dilated.^{21,44} In a like fashion, less common causes of renovascular hypertension in children, including those associated with inflammatory arteriopathies and neurofibromatosis, do not respond to renal artery PTA.

Arteriosclerosis. The largest experience with renal artery PTA has been in treating arteriosclerotic disease.^{45–60} The presence of aortic spillover arteriosclerosis versus isolated renal artery arteriosclerosis has had an important impact on long-term clinical results. Historically, PTA alone, without stent placement, has resulted in a technical success rate of only 70% to 80%. In fact, aortic spillover lesions, treated by PTA alone, have technical success rates of 30% to 50%. These latter stenoses often manifest excessive recoil and many exhibit acute dissections. As a result of high early post-PTA restenosis rates, stenting of atherosclerotic lesions is considered appropriate in these patients.

PTA with stenting for atherosclerotic renal artery disease results in outcomes that vary widely, but this therapy provides reasonable long-term technical results⁶¹ (Table 92.2). For example, Palmaz stents placed in 64 renal arteries in 59 patients resulted in a 2-year secondary patency rate of 92%.⁵² Others have documented 5-year primary and secondary patency rates of 84% and 92%, respectively.⁴⁶

PTA with stenting for progressive ischemic nephropathy is not as effective at reversing renal failure. In these cases, as with open surgical interventions, benefits appear related to the degree and duration of ischemic nephropathy prior to PTA, with those having a relative rapid onset of renal insufficiency and serum creatinine of less than 3 mg/dL demonstrating the best response.^{62–66} A number of prospective trials comparing PTA and medical therapy have concluded that PTA has only a modest but significant effect on blood pressure control.⁶⁷ The results of the prospective, randomized Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial and Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trials comparing renal artery stenting versus best medical therapy may define the incremental value of PTA revascularizations.^{54,68,69} Publication of their outcomes are being awaited by clinicians and health care insurers. Clearly, existing guidelines for renal PTA are controversial.⁷⁰

Complications accompanying renal artery PTA for fibrodysplastic disease are uncommon. PTA for arteriosclerotic disease carries a 5% to 15% risk of complications, although most are not life-threatening. Intimal disruption occurs more often with proximal renal artery dilation, where the vessel elasticity is greater and medial disruption is less likely. Medial tears are more common with distal renal artery dilation where vessel elasticity is less. The exact usefulness of embolic protection devices has yet to be defined, but they may provide improved functional outcomes following renal artery stenting and PTA for arteriosclerotic disease.^{48,71,72}

Surgical interventions following failed renal artery PTA are much more hazardous than primary surgical procedures, being associated with a higher incidence of emergent repair and nephrectomy. Blood pressure benefits occurred in 57% of cases after secondary operations for a failed renal artery PTA, compared to 89% following primary operations.⁷³

A prospective Scandinavian, randomized controlled trial comparing endovascular treatment with open surgery was performed in 1993 for the treatment of renovascular hypertension.⁷⁴ The study documented a 2-year patency rate of 75% in the PTA group versus 96% in the surgical group, but benefits regarding hypertension were equal (90%) in each group. The former study included a large number of patients crossing over from the PTA to the surgical group, leading the authors to suggest that PTA should be first-line therapy, with repeat endovascular or open surgical intervention as necessary.

Arterial Reconstructive Surgery for Renal Artery Occlusive Disease. Despite the well-documented benefits of the open surgical treatment of renovascular occlusive disease, the number of such procedures performed in the United States is declining.^{11,13,31,33,75–80} It is important that the primary revascularization procedure be successful. This point is underscored by the fact that nephrectomy accompanies nearly half of the reoperations for failed initial reconstructions. The operative mortality following primary renal artery bypass surgery in the United States has been reported to approach 10%, a figure significantly higher than that documented by most large series from individual centers.⁸¹ Operative details vary when treating the different subgroups of renal artery disease.

Aortorenal Bypass. Aortorenal bypass in adults with arteriosclerotic and fibrodysplastic occlusive disease is most often performed using autologous reversed saphenous vein (Fig. 92.14).^{11,12} Dacron or extruded Teflon conduits may also be used in reconstructing these vessels in appropriately chosen patients. Because vein grafts in children often become aneurysmal, autologous hypogastric artery grafts and direct aortic reimplantations of the renal artery are favored to reconstruct the renal arteries in pediatric-aged patients^{21,23,82} (Figs. 92.15 and 92.16).

Nonanatomic Bypass Procedures. Nonanatomic bypass procedures are important in treating certain patients with renovascular hypertension.^{77,83–86} The hepatic, splenic, or iliac arteries

FIGURE 92.14. Autogenous saphenous vein aortorenal graft. (Reproduced with permission from Stanley JC, Graham LM. Renovascular hypertension. In: Miller DC, Roon AJ, eds. *Diagnosis and Management of Peripheral Vascular Disease*. Menlo Park, CA: Addison-Wesley; 1981.)

may be used as sites of origin for bypass grafts to the renal artery, especially when originating a graft from the aorta would entail unacceptable risks. Use of the hepatic artery for a right-sided reconstruction or the splenic artery for a left-sided splenorenal bypass is appropriate in adults, but only after ascertaining that these vessels and the celiac trunk are free of stenotic disease. Splenorenal bypasses are not recommended in children because of potential celiac artery growth arrest that may evolve as the child becomes older, but which is not predictable at the time of the initial reconstruction.

Ex Vivo Renal Artery Reconstruction. Ex vivo renal artery reconstruction is an alternative means of treating select cases of renovascular hypertension, especially those involving revascularization of multiple distal segmental branches.^{80,87,88} Disadvantages of ex vivo reconstructions include the necessity to cool the kidney, longer operating times, and perhaps most important, the disruption of preexisting collateral channels.

FIGURE 92.17. Transaortic bilateral renal artery endarterectomy. Preoperative (A) and postoperative (B) aortography. (Reproduced with permission from Stanley JC, Messina LM, Wakefield TW, et al. Renal artery reconstruction. In: Bergan JJ, Yao JST, eds. *Techniques in Arterial Surgery*. Philadelphia, PA: WB Saunders; 1990:247.)

Fortunately, most renal artery reconstructions can be successfully performed in situ.

Endarterectomy. Endarterectomy is often performed for proximal renal artery arteriosclerotic disease.^{11,12,89–91} The two techniques most often used are (a) transaortic renal endarterectomy through an axial aortotomy or the transected infrarenal aorta and (b) direct renal artery endarterectomy. The extent of aortic and renal artery disease, as well as the need to perform coexistent aortic reconstructive surgery, dictates which of these procedures is most appropriate. In most cases, a linear aortotomy is begun just to the left of the superior mesenteric artery and extended in the midline to below the renal arteries. The diseased aortic arteriosclerotic tissues are elevated, and with gentle traction, the renal artery atheroma is extracted. This type of endarterectomy is particularly useful in treating bilateral disease (Fig. 92.17) or when the disease affects multiple renal arteries. Extensive plaque affecting the more distal renal artery, especially when involving bifurcations, may be better treated by a direct renal artery endarterectomy with a patch-graft closure.

Results of Operative Therapy for Renal Artery Occlusive Disease. Renal preservation and maintenance of renal function are important in assessing clinical experiences. Nephrectomy clearly does not offer as much benefit as renal revascularization. Even when nephrectomy provides good early results, it leaves the patient at considerable risk if contralateral disease evolves later. Cumulative primary and secondary nephrectomy rates for alleged unreconstructable renal artery disease in any given practice should not exceed 5%.

Surgical treatment of renovascular hypertension affords excellent outcomes.^{11,12} Differences among most individual experiences reflect variations in the prevalence of different renovascular disease categories (Table 92.3). Renovascular hypertension in childhood is most likely to exhibit a salutary outcome after restoration of normal renal blood flow (Table 92.4). Arterial fibrodysplastic renovascular hypertension (Table 92.5) is more likely to benefit from an open operation than is arteriosclerotic renovascular hypertension (Table 92.6), which is probably a reflection of coexistent essential hypertension in older patients with arteriosclerotic disease. Arteriosclerotic renovascular hypertension occurs in two subgroups of patients: (a) those with focal renal artery disease whose only clinical manifestation of

arteriosclerosis is secondary hypertension and (b) those with clinically overt extrarenal arteriosclerosis affecting the coronary, carotid, aorta, or extremity vessels. The severity and duration of hypertension, age, and gender in these two subgroups are similar, yet the surgical outcome regarding amelioration of hypertension is worse in patients with overt extrarenal arteriosclerotic disease. Open revascularization of a kidney with an occluded renal artery offers recovery of renal function and improvement in blood pressure control in nearly half the patients.^{92,93}

RENAL ARTERY ANEURYSMAL DISEASE

Aneurysms of the renal artery are unusual, but with more frequent imaging modalities are being encountered with increasing frequency.^{94–102} Complications of these aneurysms, often detected in the setting of other renal vascular disease, may have been overestimated in surgical series rather than population-based experiences. Other misperceptions regarding the importance of these aneurysms reflect unrecognized differences among their four principal types: (a) true renal artery aneurysms, (b) dissecting renal artery aneurysms, (c) aneurysmal mural dilations occurring with medial fibrodysplastic disease, and (d) arteritis-

related microaneurysms. The two renal artery macroaneurysms most relevant to surgical practice are the true aneurysms and those associated with dissections (Table 92.7).

True Renal Artery Aneurysms

The precise incidence of true renal artery aneurysms in the general population is estimated to be between 0.10% and 0.7%.^{101,103} Large reported series of these aneurysms are uncommon (Table 92.8). The group being studied bears greatly on the reported frequency of these lesions. For example, macroaneurysms have been identified in 0.7% of patients undergoing arteriographic studies directed at renal disease¹⁰⁴ and in 2.5% of those being evaluated for hypertension.¹⁰¹ Women are affected with true renal artery aneurysms slightly more often than men. However, when aneurysms in patients with arterial fibrodysplasia are excluded, there appears to be no gender predilection. The predisposition of these aneurysms to affect the right renal artery may be a reflection of the greater incidence of right-sided medial fibrodysplastic disease in women.

True renal artery aneurysms are usually located at renal artery bifurcations (Fig. 92.18). Most of these aneurysms are saccular. The average diameter of true aneurysms at the time of their clinical recognition is 1.5 cm. Extraparenchymal

FIGURE 92.18. Renal artery aneurysm at a second-order branch. (Reproduced with permission from Stanley JC, Whitehouse WM Jr. Renal artery macroaneurysms. In: Bergan JJ, Yao JST, eds. *Aneurysms*. New York: Grune & Stratton; 1982:417.)

aneurysms are very common, accounting for more than 90% of these lesions, with more than 75% occurring at first- or second-order branchings of the main renal artery.

Two distinct histologic categories of true renal artery aneurysms exist. The first type appears to be associated with a congenital elastic tissue defect or medial degenerative process. The second type of aneurysm exhibits arteriosclerosis. Atheromatous changes often occur at irregular intervals in these aneurysms, with intervening areas composed of thin, collagenous acellular fibrous tissue. In most instances, arteriosclerosis is considered a secondary event rather than a primary etiologic event.

The high frequency of renal artery aneurysms associated with medial fibrodysplasia is well recognized (Fig. 92.19). In the latter disease state, further fragmentation and disruption of elastic tissue with loss of smooth muscle at bifurcations leaves little more than a thin layer of fibrous connective tissue to contain blood flow. The greater incidence of aneurysms among patients with hypertension secondary to dysplastic renal artery stenoses, in comparison with those with arteriosclerotic stenoses, supports the tenet that arterial fibrodysplasia is a direct contributor to aneurysmal changes.

Clinical Manifestations of the True Renal Artery Aneurysms. Most renal artery aneurysms are asymptomatic, being discovered incidentally.^{85–87,91} Aneurysm expansion or renal infarction from dislodged thrombus may cause flank or abdominal pain. Hematuria and abdominal bruits have been attributed to some lesions, but are more likely due to nonaneurysmal disease. Although very uncommon, covert rupture of renal artery aneurysms into an adjacent vein may be associated with hematuria and hypertension.

Once a renal artery aneurysm is suspected, conventional catheter-based arteriography becomes the definitive diagnostic studies. However, gadolinium-enhanced magnetic resonance arteriography (MRA) and multislice three-dimensional reconstructed CT scanning (Fig. 92.20) have an increasing role in the anatomic delineation of these aneurysms.^{103,105,106}

FIGURE 92.19. Saccular renal artery aneurysm occurring at the primary bifurcation of a main renal artery exhibiting medial fibroplasia. (Reproduced with permission from Stanley JC, Whitehouse WM Jr. Renal artery macroaneurysms. In: Bergan JJ, Yao JST, eds. *Aneurysms*. New York: Grune & Stratton; 1982:417.)

The theory that renal artery aneurysms contribute to the 80% incidence of hypertension in these patients has been a subject of continual controversy.^{96,97,99,100} Embolization of aneurysmal thrombus or thrombotic occlusion of an adjacent artery may result in renal ischemia and renovascular hypertension, but this is uncommon. More often, coexisting renal artery occlusive disease in the vicinity of aneurysms may account for secondary hypertension in these patients. Indeed, renal artery stenosis may be masked by the aneurysm.¹⁰⁷ Because of this possibility, one should search for existence of occult stenoses in hypertensive patients with aneurysms.

Rupture is the most serious complication attending renal artery aneurysms. Exsanguinating hemorrhage from a ruptured renal artery aneurysm occurs rarely.^{96,108,109} Mortality with rupture is approximately 10%, but loss of a kidney is a near-universal outcome of rupture. Overt extraparenchymal rupture occurred in 2% of patients harboring these lesions, and covert rupture causing renal arteriovenous fistulas occurred in an additional 1.5%, in one of the largest reported series from a surgical group.⁹⁶ Rupture of renal artery aneurysms during pregnancy is an exception to the generally accepted benign nature of most bland aneurysms.^{110–112} Rupture of renal artery aneurysms is responsible for fetal death in nearly 85% of cases and is associated with a 55% maternal mortality rate.

An increased risk of renal artery aneurysm rupture has been attributed to large size, absence of calcification, and elevated blood pressure. However, overt rupture often has occurred in normotensive patients, as well as with calcific atherosclerotic aneurysms.^{96,110} Although greater rupture rates occurring in larger aneurysms have been only inconsistently reported, a larger size remains a logical reason to assign a greater risk of rupture.

- 6 Treatment of True Renal Artery Aneurysms.** Indications for surgical intervention for true renal artery aneurysms appears indicated in the following situations: (a) aneurysms with functionally important renal artery stenoses; (b) aneurysms harboring thrombus, especially with evidence of distal embolization and cortical infarcts; (c) aneurysms in women who plan to have children; (d) aneurysms with diameters greater than 1.5 cm in otherwise healthy patients; and (e) patients with flank pain attributed to their aneurysms. Size is

FIGURE 92.20. Computed tomography angiogram of a large renal artery aneurysm in axial cut (A, arrows) and in three-dimension (B).

the softest indication for surgical therapy. Cautious surgical intervention by those experienced in renovascular surgery in properly selected patients with renal artery aneurysms appears justified because of the small, but unpredictable, incidence of rupture with its attendant loss of kidney and life.

The objective of surgical therapy is to eliminate the aneurysm without losing the kidney or compromising its function.^{96,113,114} Most aneurysms are best approached with a transabdominal, extraperitoneal exposure of the renal vasculature following medial displacement of the overlying colon and foregut viscera. Large aneurysms of the main renal artery can usually be excised with simple primary closure of the artery, but excision of smaller aneurysms may require arterial closure with a vein patch (Fig. 92.21). More extensive renal artery reconstructions using autogenous saphenous vein or internal iliac artery as aortorenal grafts are favored for bifur-

cation aneurysms, especially those associated with functionally important stenoses of the renal artery (Fig. 92.22).

Nephrectomy is the usual therapy for managing ruptured aneurysms and extensive intraparenchymal aneurysms. Long-term outcome is actually quite good following nephrectomy in carefully selected cases. No patients treated in this manner at the University of Michigan required hemodialysis during a 20-year follow-up.⁹⁶ Nevertheless, arterial reconstruction should be considered in those instances in which the kidney does not appear to have been irreparably injured from ischemia caused by the rupture.

Endovascular treatment of renal artery aneurysms has an evolving role.^{115–121} Although endoluminal therapy appears to carry a higher risk of parenchymal infarction, no prospective comparison trials between endovascular and surgical treatments exist. Certainly, main renal artery aneurysms may be

FIGURE 92.21. A: Renal artery aneurysm located at the bifurcation of the main renal artery. B: Surgical treatment included aneurysmectomy and vein patch graft closure of the artery. (Reproduced with permission from Stanley JC. Renal artery aneurysms and dissections. In: Veith FJ, ed. *Current Critical Problems in Vascular Surgery*, vol. 3. St. Louis, MO: Quality Medical Publishing; 1991:311.)

FIGURE 92.22. Aortorenal bypass with reversed autogenous saphenous vein, following excision of an aneurysm in a fibrodysplastic vessel, with end-to-end anastomosis to one first-order segmental branch (*large arrow*) and end-to-side implantation of the other first-order segmental branch (*small arrow*). Multiple primary and segmental renal artery revascularization utilizing autogenous saphenous vein. *Surg Gynecol Obstet* 1973;137:1023–1026.)

successfully excluded by stent graft placement, and peripheral branch aneurysms can be successfully embolized. Embolization of intraparenchymal aneurysms is an appropriate alternative to partial nephrectomy in those patients with evidence of cortical infarction. Lastly, endovascular proximal arterial occlusion may be useful in hemodynamically unstable patients having a ruptured renal artery aneurysm in whom open attempts to salvage the kidney would place the patient's life at risk.

Renal artery aneurysms not treated by operation should be subjected to long-term surveillance. Because of the relatively low incidence of complications attending most renal artery aneurysms, noninvasive studies, such as abdominal ultrasonography, CT, or MRA, performed on a regular basis are favored over repeated arteriographic studies, which may carry risks exceeding those of the aneurysmal disease itself.

Renal Artery Dissections

Isolated renal artery dissections causing aneurysms are rare.^{122–126} Dissections are usually classified into two categories: (a) those due to blunt abdominal trauma or intraluminal catheter-induced injury and (b) those occurring spontaneously (Fig. 92.23). Nearly one third of renal artery dissections are bilateral. Dissections of the renal artery affect men nearly 10 times as often as women. In part, this reflects the greater likelihood of trauma-induced dissections that occur in men. Blunt abdominal trauma contributes to renal artery dissections by two specific mechanisms. The first is violent displacement of the kidney with deceleration causing marked stretching of the artery with fracture of the intima, which is the least elastic vessel wall component. This event commonly results in subintimal dissections. The second mechanism relates to traumatic compression

FIGURE 92.23. Saccular dissecting main renal artery aneurysm. (Reproduced with permission from Gewertz BL, Stanley JC, Fry WJ. Renal artery dissections. *Arch Surg* 1977;112:409–414.)

of the renal arteries against the unyielding vertebral bodies, resulting in medial hemorrhage and false aneurysm formation.

Iatrogenic, catheter-related, renal artery injury occurring during diagnostic arteriography is another recognized cause of these aneurysms. This complication is uncommon. Iatrogenic dissections usually occur within the inner media or subintimal tissues. Dissections accompanying therapeutic catheterizations, such as balloon angioplasty, are common, although only a few cause critical narrowings or occlusion of the renal artery. In these instances, stent placement usually restores normal renal artery blood flow.

Primary or spontaneous dissections causing pseudoaneurysms affect the renal arteries more than any other peripheral artery. Most are related to coexistent arteriosclerotic or dysplastic renovascular disease. A 0.5% incidence of dissections in patients with fibrodysplastic renal arteries has been reported.¹²⁷ Spontaneous dissections usually occur within the outer media adjacent to the external elastic lamina.

Clinical Manifestations of Renal Artery Dissection.

Flank and back pain, hematuria, ileus, and elevated blood pressure frequently accompany acute dissections regardless of the cause.^{123,124} Chronic renal artery dissections, when clinically relevant, are usually associated with renovascular hypertension or impaired renal function. An incorrect initial clinical diagnosis is common, occurring in more than half of patients having renal artery dissections. CT angiography can accurately define dissections and is the primary modality used most in the setting of trauma. Arteriography is used most often to diagnose and define the extent of renal artery dissections.

Treatment of Renal Artery Dissection. Trauma-related dissections warrant emergent primary arterial reconstructions once a hemodynamic narrowing or occlusion of the main renal artery or a major segmental branch is recognized. Delayed repair is necessary for less obvious trauma-related injuries if hypertension persists or renal function deteriorates. Spontaneous dissecting aneurysms, when acute, are technically easier to treat than traumatic lesions and should be subjected to surgical therapy soon after hemodynamically significant stenoses or occlusions are recognized. Operative intervention is also pursued for

chronic spontaneous dissections associated with severe renovascular hypertension or deteriorating renal function. Endovascular stent placement is an appropriate alternative therapy for short proximal renal artery dissections with a defined distal endpoint and is useful for dissections following catheter-related injuries.¹²⁸

CHAPTER 93 ■ SPLANCHNIC VASCULAR OCCLUSIVE AND ANEURYSMAL DISEASE

JOHN E. RECTENWALD, JONATHAN L. ELIASON, PETER K. HENKE, GILBERT R. UPCHURCH, Jr., AND JAMES C. STANLEY

KEY POINTS

- 1 Occlusive and aneurysmal diseases of the splanchnic vessels are relatively uncommon problems in clinical practice.
- 2 Approximately 50% of acute mesenteric ischemia cases are caused by an embolus, typically from a cardiac source. Atrial fibrillation and a myocardial infarction with mural thrombus formation are the most common embolic sources.
- 3 Acute mesenteric embolism usually results in sudden and severe epigastric or midabdominal pain, followed promptly by evacuation of the gut, with emeses or explosive diarrhea.
- 4 Complications of certain catheter-related procedures and operations are an increasingly common cause of acute ischemia.
- 5 Intestinal angina is most often a consequence of aortic spillover arteriosclerosis affecting origins of the celiac, superior mesenteric, and inferior mesenteric arteries.
- 6 In patients with chronic mesenteric ischemia, progression from minor symptoms to intestinal infarction is unpredictable.
- 7 Splanchnic artery aneurysms are uncommon, but the more frequent use of computed tomography, magnetic resonance imaging, and ultrasonography has resulted in an increase in their clinical recognition.
- 8 Splenic artery aneurysms are the most common splanchnic artery aneurysm, accounting for 60% of all splanchnic artery aneurysms.
- 9 The role of endovascular treatment of visceral artery aneurysms is becoming increasingly important, but is currently poorly defined.

- 1 Occlusive and aneurysmal diseases of the splanchnic vessels are relatively uncommon problems in clinical practice. However, it is important that physicians recognize the clinical presentations of these diseases and be knowledgeable regarding contemporary diagnostic studies and newer treatment options. For example, the “gold standard” diagnostic study, aortography with selective visceral arteriography, is being replaced with high-resolution computed tomographic angiography (CTA) or high-quality magnetic resonance angiography (MRA). In addition, endovascular techniques are displacing conventional open surgical treatment modalities for patients with these diseases.

SPLANCHNIC VASCULAR ANATOMY AND PHYSIOLOGY

The complex functions of the splanchnic viscera are supplied by a circulation uniquely adapted for absorbing and distributing nutrients. Persistence or regression of parts of the primitive visceral circulation results in important variations in the splanchnic arteries and their collateral circulation. Thus, a common celiacomesenteric trunk, replaced hepatic branches from the celiac artery to the superior mesenteric artery (SMA), and a persistent ventral anastomosis between the proper hepatic and a replaced right hepatic artery from the SMA denoted as an arch of Buhler are anatomic variations that are relevant in assessing occlusive diseases of the splanchnic circulation.¹

The vascular anatomy of the splanchnic viscera follows well-described patterns² (Figs. 93.1 to 93.4); however, the right hepatic artery has a replaced origin from the SMA in approximately 15% to 20% of the population and the left

hepatic artery is derived from the left gastric artery in about 25% of the population. In the event of occlusion or stenosis of either the celiac artery or SMA, the gastroduodenal artery becomes an important collateral vessel.

The SMA originates from the anterior surface of the aorta 1 or 2 cm below the celiac trunk. Extensive large-vessel anastomotic arcades occur among the 10 to 20 jejunal and ileal SMA branches. In addition, a well-defined anastomosis exists between the middle and left colic branches of the SMA and inferior mesenteric artery in the region of the splenic flexure. The inferior mesenteric artery arises 5 to 6 cm below the SMA, typically supplying the left half of the transverse colon and the entire descending colon through the left colic artery. The inferior mesenteric artery gives off a variable number of sigmoid branches and terminates as paired superior hemorrhoidal arteries. The marginal artery of Drummond and the arch of Riolan are discrete branch vessels capable of significant enlargement, as important collateral vessels, in the face of occlusion or stenosis of the proximal splanchnic arteries.

The venous anatomy of the gastrointestinal tract tends to parallel the arterial blood supply and drains into the portal venous system, thus perfusing the liver. The confluence of the splenic vein with the superior mesenteric vein forms the portal vein. Hepatic venous blood is drained by right, middle, and left hepatic veins, which enter the vena cava. Portal-systemic anastomoses are common and are of considerable importance in the presence of portal hypertension.

Intestinal blood flow in humans has been estimated to be between 500 and 1,200 mL/min, or about 10% to 20% of the cardiac output. Duplex ultrasound, which combines Doppler blood flow velocity determinations with B-mode grayscale images, allows precise measurement of cross-sectional areas and enables calculation of volumetric flows (Fig. 93.5). Baseline intestinal

FIGURE 93.1. The celiac artery distributes blood to the stomach, duodenum, pancreas, liver, and spleen; in addition, the gastroduodenal artery and pancreaticoduodenal arcades provide important collateral flow between the celiac and superior mesenteric arteries. The superior mesenteric artery is retropancreatic but crosses anteriorly to the fourth portion of the duodenum. It supplies blood to the duodenum and head of the pancreas, jejunum, ileum, ascending colon, and right half of the transverse colon (see Fig. 93.2). Large anastomotic arcades course between the jejunal and ileal branches.

blood flow and the response to standard meals have been established, with significant increases in SMA blood flow 20 to 30 minutes after the ingestion of food that persist for up to 90 minutes. Changes in celiac artery blood flow occur with all meal types; however, these changes are not significant (Table 93.1).

SPLANCHNIC ISCHEMIC SYNDROMES

The intestinal mucosa represents 50% of the mass of the intestine, but receives 75% of the resting blood flow. The muscular and serosal layers of the intestine receive the remaining 25%. Control of blood flow in the splanchnic circulation is affected by the sympathetic nervous system and also by metabolic, myogenic, and extrinsic factors. Stimulation of sympathetic nerves increases vascular tone and decreases splanchnic blood flow, whereas parasympathetic nerve stimulation appears to have little direct effect on blood flow. Numerous intrinsic hormones, such as secretin, gastrin, cholecystokinin, glucagon, and vasoactive intestinal peptide, in addition to substances such as histamine, serotonin, bradykinin, and the prostaglandins, all have

physiologic roles in regulating intestinal blood flow. Other substances, such as epinephrine, norepinephrine, and angiotensin, as well as many commonly used pharmaceuticals, also have important effects on the splanchnic circulation (Table 93.2).

The potential for bacterial translocation and toxin absorption add to the complexity of ischemia and reperfusion within the gut. These adverse effects exacerbate local injury and have important systemic effects, including myocardial depression and increased capillary permeability with edema formation and organ dysfunction.³⁻⁷ Loss of mucosal barrier function is clearly present in acute splanchnic ischemia, with three predisposing factors: (a) physical disruption of the mucosa, (b) a change in the normal intestinal microflora (usually resulting from treatment with broad-spectrum antibiotics), and (c) impairment of host immune defenses. The repair of mucosal damage and enhancement of host defenses appear to be facilitated by early enteral feeding and by specific nutrients, such as glutamine.

Splanchnic ischemic syndromes are most conveniently categorized as acute or chronic. However, the designation of chronic ischemia is perhaps a misnomer because even in this setting, the underlying pathophysiology is characterized by repetitive, near-critical ischemic events. Acute splanchnic syndromes include mesenteric arterial embolism, mesenteric

FIGURE 93.2. The inferior mesenteric artery (IMA) supplies blood to the left half of the transverse colon and the entire descending colon, including the sigmoid colon and rectum (via sigmoid and superior hemorrhoidal branches). The left branch of the middle colic artery, from the superior mesenteric artery, and the ascending portion of the left colic artery, from the IMA, form a collateral network in the region of the splenic flexure. The IMA serves as an important source of collateral blood supply when the proximal two visceral vessels are occluded.

FIGURE 93.3. A: The collateral circulation to the intestine occurs at several levels. Well-recognized visceral-visceral and visceral-parietal collateral branches and anastomoses are important. The unnamed intestinal arcades (B) and the intramural anastomoses (C) are effective short-segment collaterals.

FIGURE 93.3. (Continued)

arterial thrombosis, nonocclusive mesenteric ischemia (NOMI), iatrogenic ischemia, and venous thrombosis. Splanchnic ischemia severe enough to cause intestinal infarction is three times as lethal as myocardial infarction and five times as lethal as a stroke. Chronic splanchnic ischemic syndromes include arteriosclerotic mesenteric occlusive disease and the median arcuate ligament syndrome.

ACUTE SPLANCHNIC ISCHEMIA

Mesenteric Arterial Embolism

- 2 Approximately half of acute mesenteric ischemia cases are caused by an embolus, typically from a cardiac source. Atrial

FIGURE 93.4. Inferior mesenteric artery angiography demonstrates (A) the arc of Riolo, or central anastomotic artery, (B) coursing through the left upper quadrant of the abdomen, and (C) ultimately supplying the superior mesenteric artery circulation.

fibrillation and myocardial infarction with mural thrombus formation are the most common embolic sources; however, any arrhythmia or anatomic cardiac defect may result in a mesenteric embolus. Embolism of an intracardiac tumor, such as an atrial myxoma, and a paradoxical embolus resulting from venous thromboembolism and a right-to-left cardiac communication are rare causes of mesenteric ischemia.

- 3 Acute mesenteric embolism usually results in sudden and severe epigastric or midabdominal pain, followed promptly by evacuation of the gut, with emeses or explosive diarrhea. The patient can often precisely pinpoint the onset of pain, and fully 25% of patients have had previous embolic events. A

cardiac source of the embolus may be clinically evident if the patient has irregular heart rhythm, indicating atrial fibrillation, the classic murmur of mitral stenosis, or an enlarged heart. The abdominal examination may be normal initially, with signs of an acute abdomen evolving later. Slight to moderate abdominal distention is common. Bowel sounds are highly variable and not useful as a diagnostic finding. The classic presentation of acute mesenteric ischemia is severe abdominal pain that is out of proportion to minimal or absent physical findings. The presence of peritoneal signs and blood in the stool are late and ominous signs, implying intestinal infarction.

FIGURE 93.5. A: Duplex scan of the aorta and celiac and superior mesenteric arteries. Vessel diameter, flow velocity, calculated volumetric blood flow, spectral analysis, and the response to physiologic stimuli allow a precise assessment of the visceral circulation. B: Color flow Doppler scanning allows rapid identification of flow disturbances. (Courtesy of Dr. Phillip Bendick, William Beaumont Hospital, Royal Oak, MI.)

No laboratory tests are pathognomonic of acute mesenteric ischemia. Standard hematologic and biochemical studies are unrewarding early in the clinical course.⁸ Later, hemoconcentration, acidosis, leukocytosis, and elevated serum phosphorus or transaminases may be evident, yet none of these abnormalities need be present, even with a major mesenteric embolus. The diagnosis usually depends on clinical suspicion followed by characteristic anatomic findings demonstrated by angiography, computed tomography (CT) scan, or, occasionally, ultrasound. The site of embolic lodging in the SMA is often just past the inferior pancreaticoduodenal and middle colic arteries, thus isolating the small bowel from its major collateral circulation (Fig. 93.6).

In the case of a suspected diagnosis, the patient should be anticoagulated with heparin, volume resuscitated, and taken to the operating room for an emergent embolectomy. Prophylactic antibiotics and full hemodynamic monitoring are mandatory. The SMA is exposed beneath the transverse mesocolon followed by achievement of proximal and distal control of the vessel. A Fogarty catheter embolectomy is then performed through either a transverse or longitudinal arteriotomy. Primary closure with interrupted sutures can typically be performed if a transverse arteriotomy is used. Patch closure of the SMA is used if the artery is small or a longitudinal incision has been made. Intestinal viability is assessed after restoration of blood flow.

Acute Mesenteric Arterial Thrombosis

A less common cause of acute splanchnic ischemia follows thrombosis of an underlying diseased SMA. The presentation is usually less abrupt than what is typically seen with an SMA embolus, with eventual development of severe midabdominal pain. These symptoms may occur de novo, as the majority of patients with chronic mesenteric artery occlusive disease are asymptomatic, or be superimposed on a background of chronic intestinal angina. A history of motility disturbances causing nausea, diarrhea, or constipation are common but of little diagnostic value.

Urgent angiography with an anteroposterior and lateral aortogram is appropriate to establish a diagnosis of mesenteric thrombosis (Fig. 93.7). The occlusive process is usually more extensive than what is readily apparent on angiography. CTA is also being used more frequently to recognize mesenteric ischemia, and in addition to excellent vascular anatomic detail for both arterial and venous phase imaging, offers additional relevant information such as changes in the bowel wall or the presence or absence of ascites.⁹

Reperfusion of the splanchnic circulation is the major priority in these acutely ill patients. Chronic weight loss with its attendant nutritional, wound-healing, and immunologic compromise makes any operative procedure hazardous. In some

TABLE 93.1

DUPLEX MEASUREMENT OF INTESTINAL BLOOD FLOW

■ VESSEL	■ AVERAGE DIAMETER (RANGE)	■ CHARACTERISTICS ON DUPLEX SCAN	■ CALCULATED FASTING VOLUME FLOW (mL/min)	■ CALCULATED VOLUME FLOW CHANGE FROM FASTING BY TYPE OF MEAL ^a (%)

cases reperfusion can be quickly accomplished by angioplasty with or without stenting.^{10–12} These endovascular interventions may have potential benefit, even if an open revascularization were required at a later time. Nevertheless, this approach is not appropriate when peritoneal signs suggest frankly necrotic bowel requiring resection.

Operations for an acute SMA thrombosis must be individualized. Options include (a) antegrade bypasses originating from the supraceliac aorta, (b) retrograde bypasses with inflow from the iliac arteries, (c) single versus multivessel revascularization, and (d) the use of either prosthetic or autogenous venous conduit. In the presence of frankly necrotic bowel requiring resection, autogenous vein is the preferred conduit for revascularization.

Low-flow Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia remains a problem in contemporary practice.^{13,14} Vasoconstriction of the mesenteric

blood vessels is common, occurring in response to diminished cardiac output, shock, hypovolemia, dehydration, or the use of vasoactive medications (Table 93.2). This form of intestinal ischemia occurs most often in critically ill patients who are hemodynamically unstable secondary to shock or congestive heart failure. Gastrointestinal mucosal sloughing and bleeding may be present. A diagnosis in these instances may be established with angiography (Fig. 93.8). Typical findings include diffuse vasoconstriction and nonopacification of branch artery vessels. The focus of intervention is the treatment of the underlying cause of shock or cardiac dysfunction. Pharmacologic support of the circulation may also aid in relieving splanchnic vasoconstriction. Patients should receive optimization of their hemodynamic and volume status, correction of contributing medical conditions, and, when possible, elimination of adverse pharmacologic agents. Selective intra-arterial infusion of vasodilators such as intra-arterial papaverine (30 to 60 mg/h)¹⁵ or intravenous infusion of glucagon (2 to 4 mg/h) or prostaglandin E₁, which selectively increases splanchnic blood flow, has been advocated in treating this form of intestinal ischemia.^{16,17}

FIGURE 93.6. Axial section from thin slice contrasted CT demonstrates an obvious filling defect (*white arrow*) within the superior mesenteric artery due to an SMA embolus.

Iatrogenic Acute Splanchnic Ischemia

- 5 Splanchnic ischemia may also result from iatrogenic injury. Increased utilization of endovascular techniques for the treatment of occlusive and aneurysmal pathologies of the aorta and its branches may result in arterial dissections or thromboembolic events. These events are not limited to selective catheterization of the splanchnic vessels. Indeed, an atheroembolic shower from wire and/or catheter manipulation may result in

FIGURE 93.7. Lateral aortogram demonstrating acute celiac and superior mesenteric artery thrombosis, which results in widespread necrosis of the abdominal viscera.

FIGURE 93.8. Low-flow nonocclusive ischemia causes profound vasoconstriction within the mesenteric arcades, which may be sufficient to cause mucosal necrosis or transmural infarction if not relieved.

multifocal ischemic necrosis of the intestine and is a highly morbid event.

Open abdominal aortic aneurysm repair is the prototypical surgical procedure associated with iatrogenic intestinal ischemia.¹⁸ Intraoperative ligation of the inferior mesenteric artery (IMA) prior to aortic graft implantation is a typical step in this operation. The majority of patients tolerate IMA ligation without significant sequelae. However, colonic ischemia may be clinically apparent in 1% to 2% of cases and has been detected endoscopically in 6% to 8% of cases. These patients present with postoperative diarrhea and the stool is usually grossly bloody or guaiac positive. When such an event occurs, immediate colonoscopy is indicated. If the ischemia is confined to the mucosa and submucosa and subsequently heals, a stricture may form (Fig. 93.9). If the ischemia is more profound and transmural infarction occurs requiring resection, there is a 16-fold increase in mortality.¹⁹ Intestinal ischemia is also more common with ruptured aneurysms, when occlusive and aneurysmal disease coexist, and when important collateral vessels are compromised by the aortic procedure itself.

Other Types of Acute Splanchnic Ischemia

Ischemia of the intestines may also accompany aortic dissections, traumatic injuries, or the inflammatory arteritides. The clinical presentation and diagnosis depends on the underlying cause, with superimposed symptoms of abdominal distention, an acute abdomen, or gastrointestinal bleeding.²⁰ Treatment must be highly individualized. In the setting of acute aortic dissection, branch revascularization or fenestration is essential. Traumatic injuries also require urgent surgical intervention. Inflammatory arteritides require treatment of the underlying medical condition, with operation reserved only for resection of clearly nonviable bowel. Intraoperative recognition of intestinal viability, the appropriate limits to resection, and

FIGURE 93.9. Stricture formation resulting from sigmoid colon ischemia after repair of a ruptured aortic aneurysm. A loss of haustrations is seen through the descending colon and the fixed narrowing in the midportion of the sigmoid colon (arrows).

consideration of a “second-look” procedure are critical.^{21–23} Clinical parameters of color, spontaneous peristalsis, and palpable pulses are not sensitive or specific enough to provide a basis for precise and confident clinical decisions. The most common adjunctive technique to determine the extent of necessary bowel resection is Doppler ultrasonography. Fluorescein dye and Wood lamp analyses are also frequently used to assess bowel viability.

If large segments of ischemic small bowel are resected, the potential exists for the development of short-gut syndrome, in which insufficient intestine remains for adequate nutrient absorption. Contemporary clinical practice is to not resect marginally viable intestine and resect only unequivocally necrotic tissue at the initial operation. A planned “second-look” surgical procedure 24 to 48 hours later is undertaken to evaluate the status of the remaining intestine.

Mesenteric Venous Thrombosis

Thrombosis of mesenteric veins is most often subacute in its presentation. A vague prodrome of crampy abdominal pain, abdominal distention, nausea, and malaise may occur for a few days to several weeks before the disease is recognized. However, in the presence of widespread and major venous occlusions, the presentation can be acute and catastrophic. Mesenteric venous thrombosis may be secondary to an associated condition, including an intra-abdominal inflammatory process, peritonitis, portal hypertension, a hypercoagulable state, and the use of oral contraceptives. Plain films often reveal bowel wall edema. The venous phase of a selective mesenteric arteriogram may reveal the thrombus, and CT studies often demonstrate thrombus within the portal and superior mesenteric veins. In many instances, the diagnosis is made intraoperatively, with the presence of bloody ascites and dusky-appearing intestine that is thick and rubbery. The small mesenteric veins

are often cordlike and exude clot when cut. Surgical therapy consists of resection of nonviable intestine, occasional large vessel venous thrombectomy, and administration of anticoagulants. Correction of any predisposing hypercoagulable state is mandatory, such as deficiency of antithrombin III and proteins C and S, as well as the presence of factor V Leiden and anticardiolipin antibodies (the lupus anticoagulant). In cases of primary mesenteric venous thrombosis, postoperative anticoagulant therapy is continued indefinitely, because if untreated, venous thrombosis recurs in 30% to 40% of patients. Anticoagulation reduces the incidence of recurrence to 3% to 5%. In cases secondary to a treatable cause, such as peritonitis, relatively short-term anticoagulation is recommended, similar to that used when treating venous thrombosis.

CHRONIC SPLANCHNIC ISCHEMIA

Chronic Arteriosclerotic Splanchnic Ischemia

Intestinal angina is most often a consequence of aortic spillover arteriosclerosis affecting the origins of the celiac, superior mesenteric, and inferior mesenteric arteries. The responsible anatomic lesions invariably involve at least two of these three arteries (Fig. 93.10). The occlusive process may also be widespread throughout the mesenteric arcades, especially in diabetics. The patient is either typically affected with generalized clinical overt arteriosclerosis or is a relatively young woman with an extensive cigarette-smoking habit.

These patients develop “food fear” and modify their pattern of eating so that they only consume small quantities of food at any one time. Intestinal angina may manifest as periumbilical discomfort, developing 15 to 30 minutes after eating and often lasting 1 to 4 hours. Patients with chronic splanchnic ischemia almost always have a profound weight loss, which raises the specter of an intra-abdominal malignancy. Many times, gastrointestinal contrast studies, endoscopy, various scans, and nonproductive exploratory laparotomies have been undertaken before a diagnosis of intestinal ischemia is considered.

6 The progression from minor symptoms to intestinal infarction is unpredictable. Frequently, patients with intestinal infarction are discovered, in retrospect, to have had preexisting symptoms of intestinal angina. Although delayed recognition is commonplace, therapeutic interventions must proceed expeditiously, because if intestinal angina progresses to transmural infarction, it is attended by an 80% mortality rate.

Duplex scanning, MRA, and CT scans support the diagnosis of this form of intestinal vascular disease. Aortography, including both anteroposterior and lateral views, however, has most commonly been used to assess this disease (Fig. 93.11). In some clinical series, 85% of the celiac, superior mesenteric, and inferior mesenteric arteries were totally occluded or severely stenotic.²⁴ Although often diseased, the inferior mesenteric artery frequently serves as the major remaining source of blood flow to the gut, with an occluded celiac artery and SMA. At the very least, duplex scanning of the aorta and visceral vessels should be undertaken in suspected cases. MRA, CTA, or conventional angiography can then be pursued when appropriate.^{25–27}

Elective intestinal revascularization using an endovascular or open surgical approach is standard therapy in the treatment of arteriosclerotic chronic mesenteric ischemia.^{20,28–37} For open revascularization, multiple-vessel revascularization with short, antegrade conduits of either autogenous saphenous vein or prosthetic material is favored (Fig. 93.12). A variety of other bypass techniques have also resulted in long-term relief of symptoms (Fig. 93.13). Endarterectomy through a “trapdoor” aortotomy with a thoracoabdominal exposure (Figs. 93.14 and 93.15) is particularly effective

FIGURE 93.10. (A) Celiac artery stenosis and superior mesenteric artery occlusion are apparent in this lateral aortogram. (B) Lateral aortogram following primary stenting of the celiac artery, and recanalization and stenting of the superior mesenteric artery.

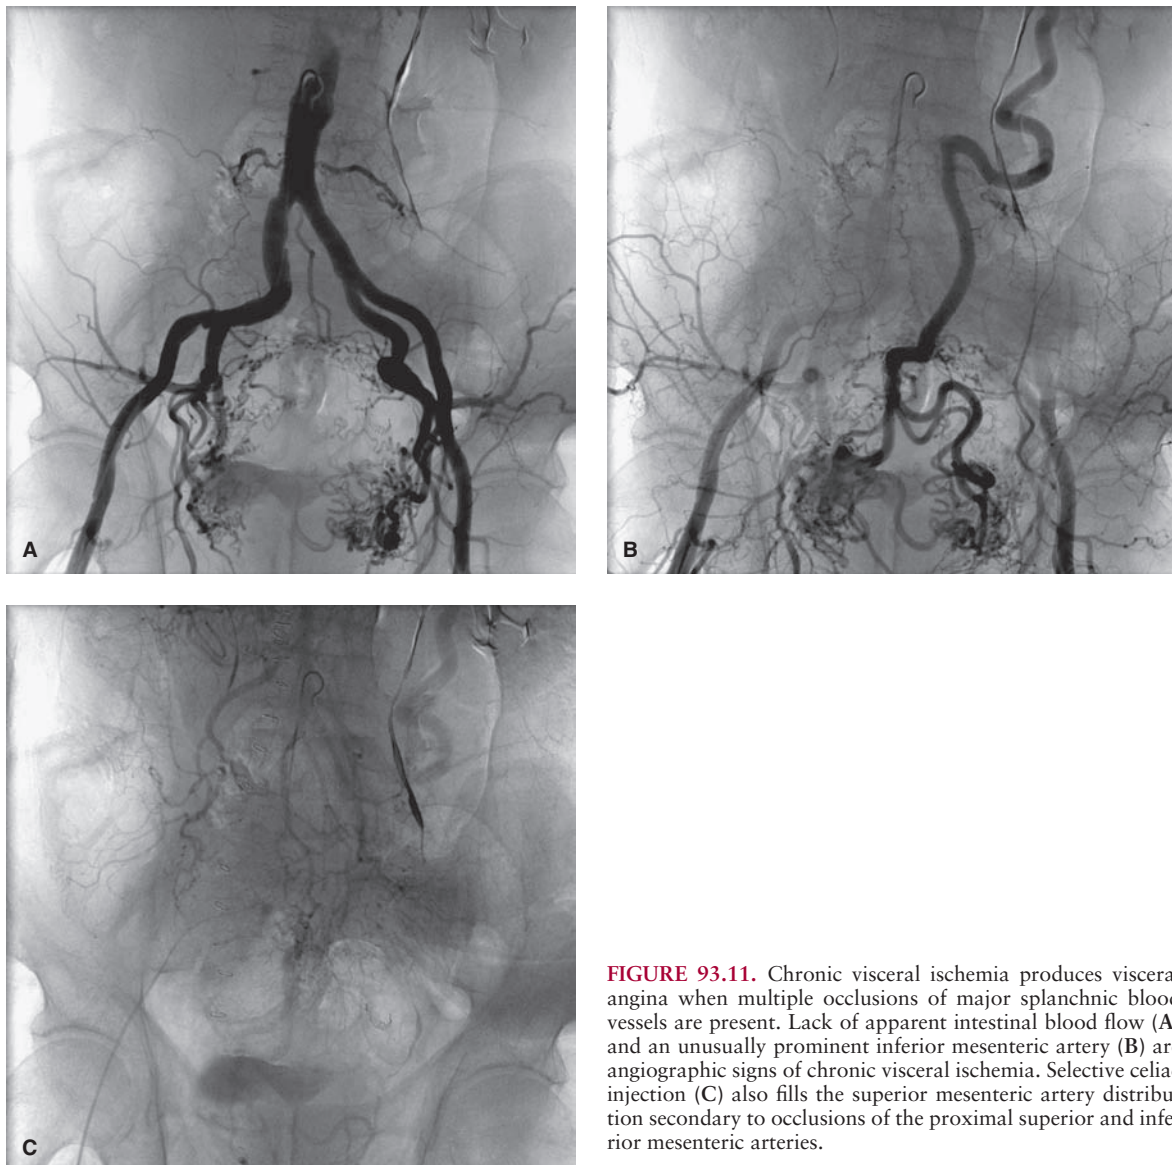

FIGURE 93.11. Chronic visceral ischemia produces visceral angina when multiple occlusions of major splanchnic blood vessels are present. Lack of apparent intestinal blood flow (A) and an unusually prominent inferior mesenteric artery (B) are angiographic signs of chronic visceral ischemia. Selective celiac injection (C) also fills the superior mesenteric artery distribution secondary to occlusions of the proximal superior and inferior mesenteric arteries.

FIGURE 93.12. Bypass grafts to the visceral vessels may originate from the supraceliac aorta. Short antegrade conduits and multiple-vessel revascularization are favored.

when multiple proximal intestinal arterial stenoses or occlusions, as well as concomitant renal artery lesions, are present. Percutaneous angioplastic procedures with or without endoluminal stenting are often used. Although long-term follow-up data are lacking when compared to follow-up for open repair, initial results suggest a favorable morbidity and mortality profile with perhaps higher rates of symptom recurrence in the endovascular group.^{34,38–50}

Median Arcuate Ligament Syndrome

Symptomatic entrapment of the celiac artery by the median arcuate ligament is controversial. Symptoms include postpran-

dial periumbilical abdominal pain, but this symptom may or may not represent intestinal ischemia. Arteriography in these patients reveals a significant compression of the celiac artery by the median arcuate ligament of the diaphragm (Fig. 93.16). Lysis of the overlying median arcuate ligament and surrounding neural tissue affords relief of symptoms in approximately half of these patients, with celiac axis revascularization required, either surgical or endovascular, in an occasional case.

SPLANCHNIC ARTERY ANEURYSMAL DISEASE

- 7 True splanchnic artery aneurysms are uncommon, but the more frequent use of CT, magnetic resonance imaging (MRI), and ultrasonography has resulted in an increase in their clinical recognition (Table 93.3). Prompt recognition of these aneurysms is clearly clinically important considering that nearly 22% present as surgical emergencies, including 8.5% that result in the patient's death. The splanchnic vessels involved with these macroaneurysms, in decreasing order of frequency, are the splenic, hepatic, superior mesenteric, celiac, gastric–gastroepiploic, jejunal–ileal–colic, pancreaticoduodenal–pancreatic, and gastroduodenal arteries (Table 93.3). The general clinical manifestations and management of these aneurysms, including the more widespread use of endovascular interventions, have been addressed in a number of recent reviews.^{51–60} Although surgical management of splanchnic artery aneurysms remains the mainstay of treatment, endovascular techniques are being increasingly applied to these aneurysms in the setting of rupture⁶⁰ and may be the preferred treatment in those patients who are deemed high surgical risk, or for aneurysms in locations that are difficult to approach surgically.⁶¹ However, the specifics of each of these splanchnic artery aneurysms deserve individual consideration.

Splenic Artery Aneurysm

- 8 Splenic artery aneurysms account for 60% of all splanchnic artery aneurysms. The occurrence of these lesions in the general population is probably similar to the 0.78% incidence in

FIGURE 93.13. Retrograde conduits are an alternative bypass, and even single-vessel revascularization may provide effective long-term relief of symptoms in selected circumstances. **A:** Retrograde right external iliac artery to superior mesenteric artery (SMA) vein graft. Filling is excellent throughout the distribution of the SMA and in the branches of the celiac artery as a result of collateral flow through the gastroduodenal artery. **B:** A left common iliac artery–SMA bypass.

nearly 3,600 consecutive patients undergoing abdominal arteriographic studies for reasons other than suspected aneurysmal disease.⁶² Women are four times more likely than men to develop splenic artery aneurysms.

The predilection for these aneurysms to affect the splenic artery reflects a peculiar group of associated disorders having an effect on the vasculature. Three distinct factors may contribute to the development of splenic artery aneurysms, including two that account for their unusual female predilection. The first factor is medial fibrodysplasia, which usually occurs in women and is most often manifested by renal artery stenosis and secondary hypertension. Approximately 2% of patients with renal artery fibrodysplasia have splenic artery aneurysms, and all of these patients have been women.⁶² Systemic hypertension may contribute to aneurysm expansion in these patients. The second factor relates to the vascular consequences of pregnancy, with its known increase in splenic blood flow and reproductive hormone-related changes in elastic tissue. This factor becomes a particular problem with repeated pregnancies. Approximately 40% of women harboring these lesions have completed six or more pregnancies.^{62,63} The third factor is evident in the nearly 10% of patients with portal hypertension and splenomegaly who develop splenic artery aneurysms.^{62,64,65} In these cases, the vessel wall integrity may be compromised by increased splenic blood flow^{66,67} and excessive estrogen activity occurring as a consequence of the underlying cirrhosis. Although splenic artery aneurysms have been described with regularity among patients after orthotopic liver transplantation,^{68–71} it is speculative as to whether these represent preexisting aneurysms associated with portal hypertension or have arisen as a consequence of the transplant and attendant drug therapy, such as steroids.⁶⁸ Aneurysms in the latter patients are more likely to affect women and appear directly related to the severity of the preexisting portal hypertension.⁷⁰ Rare splenic artery aneurysms appear associated with developmental anomalies of the foregut arterial circulation.^{72,73}

FIGURE 93.17. Splenic artery aneurysm exhibiting marked fibrosis cholesterol clefts and with calcific arteriosclerosis (hematoxylin-eosin, decalcified, $\times 32$).

Certain splenic artery aneurysms exhibit extensive arteriosclerosis (Fig. 93.17). The fact that calcific arteriosclerotic changes appear limited to the aneurysm and not the intervening artery suggests that this is more likely a secondary event, rather than a primary etiologic process. Arterial disruptions caused by periarterial inflammatory disease, such as chronic pancreatitis, or penetrating trauma are less common causes of these aneurysms. Microaneurysms of smaller intraparenchymal splenic arteries are usually caused by a systemic vasculitis, such as polyarteritis nodosa, and appear to be of less clinical importance as a vascular disease than extraparenchymal aneurysms attributed to other causes.

Most aneurysms involving the distal splenic artery are sacular and occur at branchings. At such sites, discontinuities exist in the internal elastic lamina of normal vessels, and any subsequent degenerative events involving elastic tissue, as might occur with arterial fibrodysplasia or pregnancy, are likely to produce aneurysmal changes (Fig. 93.18). Such aneurysms are multiple 20% of the time, in contrast to those in patients undergoing liver transplantation for cirrhosis-related portal hypertension where multiple aneurysms occur in 90% of patients. Proximal aneurysms of the main splenic artery are usually solitary and are frequently associated with arterial erosions by pancreatitis-related pseudocysts (Fig. 93.19).

FIGURE 93.18. Splenic artery aneurysm exhibiting fragmentation of internal elastic lamina and medial dysplasia in a patient having renal arterial fibrodysplasia (Masson stain, $\times 32$).

FIGURE 93.19. Splenic artery aneurysm. Arteriogram documents a pancreatitis-related aneurysm affecting the mid-splenic artery. (Stanley JC, Frey CF, Miller TA, et al. Major arterial hemorrhage: a complication of pancreatic pseudocysts and chronic pancreatitis. *Arch Surg.* 1976;111:435–440, with permission.)

Vascular calcifications on plain abdominal radiographs may be the first clinical evidence of a splenic artery aneurysm. The most characteristic of these findings are signet-ring calcifications (Fig. 93.20). However, contemporary diagnoses of splenic artery aneurysms usually follow their arteriographic demonstration during studies for nonvascular diseases. Color flow Doppler ultrasonography, CT, and MRI often establish the presence of these lesions and are often useful in identifying bleeding aneurysms.^{74,75} These studies are also useful in following asymptomatic splenic artery aneurysms.

Left upper quadrant or epigastric pain may occur in patients with an intact splenic artery aneurysm. In a recent review, nearly half the patients with these aneurysms complained of abdominal pain.⁵⁸ However, the literature tends to include more spectacular cases and most bland aneurysms are likely to be asymptomatic.

In cases of splenic artery aneurysm rupture, bleeding is usually initially contained within the lesser sac, with later hemorrhage into the peritoneal cavity, and causes vascular collapse.

FIGURE 93.20. Splenic artery aneurysm. Curvilinear signet ring-like calcification in the left upper quadrant characteristic of a splenic artery aneurysm. (Reproduced with permission from Stanley JC, Thompson NW, Fry WJ. Splanchnic artery aneurysms. *Arch Surg* 1970;101:689–697.)

This represents the so-called double-rupture attributed to splenic artery aneurysms. Pancreatitis-related aneurysms are not usually associated with intraperitoneal bleeding. They are more commonly a source of intestinal hemorrhage after rupture into the stomach or pancreatic ductal system.^{76–80} Arteriovenous fistula formation after splenic artery aneurysm rupture into an adjacent splenic vein is rare.⁸¹ Gastrointestinal hemorrhage from esophageal varices due to left-sided portal hypertension may accompany these fistulas.

The risk of splenic artery aneurysm rupture depends on a number of confounding and poorly defined factors. In general, rupture of bland aneurysms occurs in less than 2% of cases.⁶² Contrary to prior tenets, rupture appears just as likely when the aneurysm is calcified, occurs in a normotensive patient, or occurs in the very elderly patient. Bland aneurysms associated with liver transplants rupture twice as often as in other patients,^{68,69} and such is a fatal complication in over half of transplant patients.⁸²

Nearly 95% of aneurysms recognized during pregnancy have ruptured.^{62,83–86} The maternal mortality rate approaches 75%, and the fetal mortality rate exceeds 95% in these cases.⁸⁷ Pregnancy-related rupture occurs most often during the third trimester (69%) and is less common during the first two trimesters (12%), during labor (13%), or postpartum (6%).⁸⁵ Given the fact that most women develop these aneurysms with repeated pregnancies, it is reasonable to assume that most aneurysms in pregnant women go unrecognized and do not rupture. Nevertheless, splenic artery aneurysms in pregnant patients must be considered a threat to the life of the mother and fetus.

The reported mortality rate accompanying an open operation for rupture of a bland splenic artery aneurysm unassociated with pregnancy is 25%.⁶³ Thus, it would seem ill advised to undertake elective operative intervention for an asymptomatic splenic artery aneurysm if the surgical mortality rate exceeds 0.5%. This latter figure represents the product of the predicted 2% rupture rate of bland aneurysms and the known 25% risk of operative death when treating a patient following aneurysmal rupture. If intervention becomes necessary in higher-risk patients, then percutaneous transcatheter embolization of the aneurysm may represent a more appropriate therapy.

Splenectomy has been the most common form of open surgical therapy for splenic artery aneurysms in the past. However, because of the immunologic importance of the spleen even in the aged, simple ligature obliteration or excision of these aneurysms appears preferable to splenectomy.⁸⁸ Laparoscopic ligation of these aneurysms in certain instances may prove quite feasible.^{89,90} Treatment of splenic artery aneurysms embedded in pancreatic tissue, especially those associated with pancreatitis, may require distal pancreatectomy.⁹¹ In some of these cases, especially false aneurysms caused by pseudocyst erosion into the artery, treatment may entail incising the aneurysmal sac and ligating entering and exiting vessels from within. Pancreatic resection or cyst drainage in these latter cases must be individualized and depends on the extent and chronicity of the associated pancreatic inflammatory disease.

Percutaneous transcatheter embolization of splenic artery aneurysms (Fig. 93.21) often is preferred over an open operative intervention.^{92–95} However, careful follow-up of endovascular-treated patients is mandatory. Splenic infarction, splenic abscess formation, and late rupture are legitimate concerns after splenic artery coil embolization. Further concerns center around issues such as transient obliteration of the aneurysm or coil migration and erosion into the adjacent viscera.^{96,97} For example, coil migration into the stomach after splenic artery aneurysm treatment has been described.⁹⁶ Patients with multiple splenic artery aneurysms, especially near the hilum of the spleen, appear to be at particular risk for major complications.⁹⁸ Stent graft exclusion of an aneurysm with maintenance of splenic artery flow has been used in select cases,^{99–101} but

FIGURE 93.21. A: A 3.5 cm saccular splenic artery aneurysm on selective mesenteric angiogram. B: Completion splenic artery angiogram after embolization of the splenic artery. Vascular plugs (*white arrows*) in the splenic artery proximal and distal to the aneurysm.

can be particularly challenging and can result in dissection or thrombosis of the splenic artery from placement of the large-diameter catheters currently required for stent graft delivery into the tortuous artery or from apposition of the posterior wall of the artery to the relatively stiff stent lumen occluding the lumen of the stent graft (“T-bar” phenomenon).

Hepatic Artery Aneurysm

Hepatic artery aneurysms account for 20% of all previously reported splanchnic artery aneurysms (Fig. 93.22). These aneurysms are being encountered more frequently in contemporary times, and in some series outnumber splenic artery aneurysms.^{58,102} Men have been twice as likely to be affected as women in the past, although gender differences are not as apparent in recent experiences.^{58,103} Hepatic artery macroaneurysms are usually solitary. Large aneurysms tend to be saccular, and aneurysms less than 2 cm are usually fusiform. These aneurysms are extrahepatic in nearly 80% of cases and intrahepatic in 20%. More than one third of patients with hepatic artery aneurysms have other splanchnic aneurysms.¹⁰⁴

Most noninfectious and nontraumatic hepatic artery aneurysms are usually recognized after the sixth decade of life.

FIGURE 93.22. Hepatic artery aneurysm. Selective celiac arteriogram demonstrates a large saccular aneurysm at the bifurcation of the proper hepatic artery. (Reproduced with permission from Zelenock GB, Stanley JC. Splanchnic artery aneurysms. In: Rutherford RB, ed. *Vascular Surgery*. Philadelphia, PA: WB Saunders; 2000:1369.)

The cause of many hepatic artery aneurysms is poorly defined. Two facts regarding the cause of these aneurysms are noteworthy. First, arteriosclerosis most likely represents a secondary event rather than a primary cause of these aneurysms. Most of these lesions probably occur as a result of medial degeneration. Second, with increasing societal violence and intravenous substance abuse, the number of reported traumatic and infection-related aneurysms has markedly increased⁵⁸ (Fig. 93.23). Another common cause of intrahepatic pseudoaneurysms is arterial injury accompanying invasive percutaneous diagnostic and therapeutic procedures involving penetration of the liver.^{105,106} Nearly 17% of these aneurysms encountered more recently have occurred in orthotopic liver

FIGURE 93.23. Traumatic hepatic artery aneurysm. Blunt abdominal injury and gunshot wounds cause most traumatic lesions. (Reproduced with permission from Whitehouse WM Jr, Graham LM, Stanley JC. Aneurysms of the celiac, hepatic, and splenic arteries. In: Bergan JJ, Yao JST, eds. *Aneurysms: Diagnosis and Treatment*. New York: Grune & Stratton; 1981:405.)

transplant patients.⁵⁸ Systemic arteriopathies, such as periarteritis nodosa, have been incriminated as a cause of occasional macroaneurysms, but are more often associated with intraparenchymal microaneurysms.¹⁰⁷

Hepatic artery aneurysms may be suspected because of displacement of or indentations on intestinal structures noted on barium contrast studies. Most contemporary diagnoses of these aneurysms result from their incidental recognition during arteriography, CT, or ultrasonography for nonvascular disease. Few hepatic artery aneurysms are symptomatic. When they become symptomatic, most present with right upper quadrant or epigastric pain. Rapid expansion of these aneurysms may cause severe discomfort similar to that of acute pancreatitis. Large aneurysms have been reported to cause obstructive jaundice, although most hepatic artery aneurysms are too small to compress the major bile ducts. These lesions rarely present as pulsatile abdominal masses.

The reported incidence of hepatic artery aneurysm rupture approaches 20%, but the contemporary rate may be less. It is certainly less than the often-quoted rupture rate of 44% in cases reported a few decades ago.⁶³ Aneurysm rupture is associated with a 35% mortality rate, although in recent times the mortality appears less.⁵⁸ Bleeding from a ruptured hepatic artery aneurysm occurs with equal frequency into the biliary tract and peritoneal cavity. Hemobilia accompanies the former, being manifest by biliary colic, hematemesis, and jaundice.¹⁰⁸ Chronic, relatively asymptomatic hemorrhage is an uncommon sequela of aneurysm rupture into the biliary tract. Intrapertitoneal bleeding is usually caused by rupture of inflammatory-related false aneurysms.

Common hepatic artery aneurysms are often treated by aneurysmectomy or aneurysm exclusion, without arterial reconstruction. The extensive hepatic arterial collateral circulation and parallel portal venous circulation often ensure adequate blood flow to the liver with interruption of the proximal common hepatic artery. Liver necrosis is more likely to follow ligation of arteries in the more distal hepatic circulation. Nevertheless, even in the latter vessels, complex arterial reconstructions should be avoided and simple ligation undertaken if temporary intraoperative occlusion of the involved artery does not result in obvious hepatic ischemia. If liver blood flow appears inadequate with such a maneuver, then hepatic artery reconstruction should be undertaken using either prosthetic or autologous vein grafts. In the case of rapidly bleeding ruptured intraparenchymal aneurysms, hepatic territory resection may be necessary therapy.

Percutaneous transcatheter obliteration of hepatic artery aneurysms with balloons, coils, or thrombogenic particulate matter is often a preferred alternative to open surgical intervention.^{58,92,106,109,110} One must realize that transcatheter embolization may be only transiently successful, and repeated embolization or surgical therapy may subsequently be required to adequately treat these patients.^{94,109} Hepatic artery coil embolization may be the preferred treatment for small intrahepatic pseudoaneurysms, especially in those patients with malignancies.¹¹¹ The reported 42% recanalization rate following hepatic artery embolic occlusion is noteworthy and mandates thoughtful postembolization follow-up. Stent graft repair of hepatic artery aneurysms has been described in the literature.^{111,112} In the author's limited experience, stent grafts placed in the hepatic artery for treatment of aneurysm cause slowly progressive stenosis of the hepatic artery and the artery eventually occludes. In a small number of cases sufficient hepatic collaterals to the liver develop by the time of occlusion and the liver parenchyma remains viable. The potential for migration of embolic material or stent graft occlusion with central lobular necrosis and abscess formation is also a recognized complication of transcatheter treatment of these aneurysms. Percutaneous thrombin injection of a hepatic artery pseudoaneurysm has been reported in a liver transplant patient following repair of a perforated duodenum in the setting of bile peritonitis.¹¹³

Transcatheter thrombin injection, coil embolization, and endograft exclusion of select aneurysms may prove useful in carefully chosen patients.^{113–115}

Superior Mesenteric Artery Aneurysm

Aneurysms of the proximal SMA account for 5.5% of all splanchnic artery aneurysms. These lesions affect men twice as often as women. Infection from a cardiac source has been a common cause of these aneurysms in the past,^{63,115} but are less common in recent times.¹¹⁶ Nonhemolytic streptococci, as well as many common pathogens accompanying parenteral substance abuse, cause bacterial endocarditis and are the underlying source of infection in most cases. Many of these aneurysms are associated with intramural dissections (Fig. 93.24).¹¹⁷ SMA aneurysms may also be caused by medial degeneration, periarterial inflammation, and trauma. Arteriosclerosis, as in the case of other splanchnic aneurysms, is usually a secondary process. SMA aneurysms are often recognized during arteriographic studies for nonvascular disease (Fig. 93.25).^{59,116}

Although many patients with SMA aneurysms are asymptomatic, the majority of patients have abdominal discomfort, often suggestive of intestinal angina. SMA aneurysm rupture is not common, and in the past was considered rare.^{116,117} The mortality rate with rupture approaches 50%.¹¹⁸ Gastrointestinal hemorrhage associated with these aneurysms often accompanies their acute occlusion with bleeding into areas of intestinal infarction. Location of most aneurysms near the origins of the inferior pancreaticoduodenal and middle colic arteries isolates the distal mesenteric circulation when dissections or occlusions occur. In these circumstances, intestinal ischemia develops because the usual collateral network from the adjacent celiac and inferior mesenteric arterial circulations is obstructed.

FIGURE 93.24. Superior mesenteric artery aneurysm. Microscopic cross section of a dissecting aneurysm affecting the proximal superior mesenteric artery (hematoxylin-eosin, $\times 20$).

FIGURE 93.25. A: A 4-cm fusiform aneurysm of the superior mesenteric artery on three-dimensional computed tomographic angiographic imaging. There is an incidental finding of a 1.5 cm celiac artery aneurysm as well. B: Cross-sectional imaging of the same superior mesenteric aneurysm (between white arrows).

Operative management of SMA aneurysms is best accomplished by aneurysmectomy or aneurysm exclusion, followed by intestinal revascularization if needed with an aortomesenteric graft. Because of potential infection when bowel ischemia is present, autologous vein or artery is favored over prosthetic conduits for these reconstructions. SMA aneurysm ligation without arterial reconstruction may be successful in patients who have developed an adequate collateral circulation to their midgut. In fact, ligation and aneurysmorrhaphy have been the most commonly reported means of managing these aneurysms.^{114,119–121} Temporary intraoperative occlusion of the SMA with Doppler documentation of adequate intestinal blood flow should be undertaken before proceeding with SMA ligation.

Endovascular stent graft placement for select SMA aneurysms has appeal,^{122,123} although infection and thrombosis may compromise this type of treatment. Obliteration of these aneurysms by coils or direct thrombin injection may be preferred in high-risk patients having discrete aneurysm necks and adequate collateral circulation to the distal SMA.^{116,124}

Celiac Artery Aneurysm

Celiac artery aneurysms account for 4% of all splanchnic artery aneurysms. Men and women appear equally affected. Those aneurysms encountered before 1950 were usually infectious in etiology, but in contemporary times have been associated with medial degeneration.^{125,126} Arteriosclerosis is a common histologic finding that is considered a secondary event rather than an etiologic process. Other splanchnic artery aneurysms affect nearly 40% of these patients. Celiac artery aneurysms are usually sacular, and most are located in the distal vessel (Fig. 93.26).

Most celiac artery aneurysms are asymptomatic or appear to be associated with vague abdominal discomfort.^{58,59} These aneurysms are usually recognized during ultrasonography, angiography, or other imaging studies for nonvascular diseases.

In more recent times, rupture has affected 13% of these aneurysms and carried a mortality rate of 50%.¹²⁵ In contrast, rupture rates published before 1950 were often higher than 80%. Rupture usually causes exsanguinating intraperitoneal hemorrhage. Although rare, gastrointestinal bleeding may follow rupture of the aneurysm into the stomach or pancreatic ductal system.

Aneurysmectomy with celiac artery reconstruction is the preferred treatment for these lesions, although aneurysm exclusion with ligation of its branches has been performed successfully in select patients.^{125–128} When simple ligature is

FIGURE 93.26. Celiac artery aneurysm. Aortogram reveals sacular aneurysm that exhibited medial degenerative changes and secondary arteriosclerosis. (Reproduced with permission from Stanley JC, Whitehouse WM Jr. Aneurysms of the splanchnic and renal arteries. In: Bergan JJ, Yao JST, eds. *Surgery of the Aorta and Its Body Branches*. Orlando, FL: Grune & Stratton; 1979:497.)

undertaken, the adequacy of the liver's collateral circulation must be documented. If liver ischemia is apparent after temporary intraoperative celiac artery occlusion, then hepatic revascularization becomes mandatory. An aortoceliac or aortohepatic artery bypass in these circumstances is best performed with either an autologous vein or prosthetic graft. Surgical therapy of celiac artery aneurysmal disease has been successful in more than 90% of cases.

Endovascular obliteration of a celiac artery aneurysm is not often considered because of the need to occlude the hepatic, splenic, and left gastric arteries, and perhaps the inferior phrenic arteries, in order to isolate the aneurysms. Nevertheless, in select cases catheter-based therapy may be successful.¹²⁹ Embolic occlusion of the celiac trunk with glue and treatment with coil embolization and stent graft placement have been described in the literature as viable techniques for endovascular management of celiac artery aneurysms.^{111,129-131} One report describes celiac artery occlusion in a variety of aneurysms including thoracoabdominal aortic aneurysms and dissections, as well as celiac artery aneurysms. The authors report treatment of three true aneurysms of the celiac artery with coil embolization of the celiac branch vessels in two cases and of the celiac artery alone in one. There were no treatment-related complications in any case, but care was taken to ensure that collateralization to the proper hepatic artery remained intact after celiac artery or branch embolization. Normal liver function was considered a prerequisite for embolic treatment of these aneurysms.¹³⁰ Successful treatment of a large (10-cm) sacular celiac artery pseudoaneurysm in a high-risk surgical patient by exclusion of the celiac artery with an aortic stent graft has also been described.¹³¹

Gastric and Gastroepiploic Artery Aneurysms

Gastric and gastroepiploic artery aneurysms account for 4% of all splanchnic artery aneurysms (Fig. 93.27). Gastric artery aneurysms occur 10 times more often than gastroepiploic artery aneurysms. Men are three times more likely than women to develop these aneurysms. Most of these perigastric lesions have been encountered in patients older than 50 years of age. These aneurysms usually are solitary, occurring as a result of periarterial inflammation or medial degeneration. In many cases, there is an antecedent history of peptic ulcer disease. Arteriosclerosis, when present, is considered a secondary event, not a cause of these lesions.

FIGURE 93.27. Gastroepiploic artery aneurysm. Selective celiac arteriogram revealing small aneurysm responsible for massive gastrointestinal hemorrhage. (Reproduced with permission from Stanley JC, Thompson NW, Fry WJ. Splanchnic artery aneurysms. *Arch Surg* 1970;101:689-697.)

Most reported gastric or gastroepiploic artery aneurysms have been symptomatic when initially recognized, frequently presenting as emergencies.¹³²⁻¹³⁴ Rupture has accompanied more than 90% of reported cases, with gastrointestinal bleeding occurring slightly more than twice as often as intraperitoneal hemorrhage. Rupture carries a 70% mortality rate.⁶³ These figures may overestimate the seriousness of these aneurysms, with reported cases often spectacular and unrepresentative of the usual case.

Surgical treatment is recommended for all gastric and gastroepiploic artery aneurysms.⁸ Vascular reconstructive surgery is not required in these cases. Intramural gastric aneurysms may be excised with a small segment of involved stomach, whereas extramural aneurysms can be treated by arterial ligation alone, with or without aneurysm excision. Certain lesions may be treated by a laparoscopic approach.¹³⁵ Intraoperative identification of these small aneurysms is often tedious if preoperative localization has not been established by arteriographic studies.

Endovascular occlusion of life-threatening bleeding from a ruptured aneurysm may be appropriate as a prelude to definitive open surgical aneurysmectomy or as potentially definitive treatment in select cases. There are multiple case reports in the literature describing catheter-based treatment of gastric artery aneurysms including treatment with embolization,^{53,136} thrombin injection,¹³⁷ and even stent graft placement with preservation of arterial flow through the vessel.¹³⁸ The role of endovascular techniques in treatment of gastric and gastroepiploic artery aneurysms is evolving and will likely not be well defined in the near future due to the infrequent occurrence of these aneurysms.

Jejunal, Ileal, and Colic Artery Aneurysms

Aneurysms of the jejunal, ileal, and colic arteries account for 3% of all splanchnic artery aneurysms (Fig. 93.28). They usually occur in patients older than 60 years of age. Men and women are affected equally. Multiple aneurysms have been encountered in 10% of cases. Acquired medial defects cause most of these lesions. Although arteriosclerosis is present with 20% of these aneurysms, it is considered to represent a secondary event, not an etiologic process. An increasing number of mycotic aneurysms affect these vessels, developing as the

FIGURE 93.28. Ileal artery aneurysm. Mesenteric arteriogram documenting saccular aneurysm of distal ileal artery. (Reproduced with permission from Zelenock GB, Stanley JC. Splanchnic artery aneurysms. In: Rutherford RB, ed. *Vascular Surgery*. Philadelphia, PA: WB Saunders; 2000;1369.)

sequela of infected emboli originating from subacute bacterial endocarditis.¹³⁹ Periarteritis nodosa is also a common underlying cause of multiple aneurysms affecting these intestinal branch arteries.¹⁴⁰ Most aneurysms of these vessels have been reported to cause abdominal pain, yet many are first recognized as incidental findings during arteriography for gastrointestinal bleeding.^{63,141} Jejunal, ileal, and colic artery aneurysms are reported to have ruptured in 30% of cases, but actual rupture rates are probably a third of that figure. Rupture is associated with a mortality rate of 20%. Aneurysmal rupture usually occurs into the gastrointestinal tract. Rupture into the mesentery or peritoneal cavity is uncommon.

Operation for intestinal branch aneurysms is recommended in all instances, except for bland aneurysms associated with connective tissue diseases. Expedient surgical therapy requires careful preoperative localization with arteriographic studies. Arterial ligation, with or without aneurysmectomy, is recommended in treating extraintestinal lesions, whereas intramural aneurysms and those associated with bowel infarction require resection of the involved intestine. In select patients transcatheter embolization may be undertaken, although intestinal necrosis with perforation or late stricture formation is a recognized complication of such therapy.¹⁴² Inferior mesenteric artery aneurysms represent a unique subset of these mesenteric aneurysms.^{143,144} They are quite rare and their etiology so varied that the clinical importance of them has not been clearly established.

Endovascular treatment of this subset of visceral artery aneurysms is present but poorly described in the literature.^{145,146} However, embolization of jejunal, ileal, and colic arterial vessels is certainly a well-described and accepted method of treatment in the setting of gastrointestinal bleeding and treatment of endoleaks after endovascular abdominal aortic aneurysm repair. Furthermore, given the difficulties associated with open surgical approaches in locating and surgically repairing these aneurysms, endovascular treatment of these aneurysms remains an attractive and increasingly utilized method of treatment.

Pancreaticoduodenal, Pancreatic, and Gastroduodenal Artery Aneurysms

Pancreatic and pancreaticoduodenal artery aneurysms (Fig. 93.29) account for 2% of all splanchnic artery aneurysms, and

FIGURE 93.29. Inferior pancreaticoduodenal artery aneurysm. Selective superior mesenteric arteriogram revealing false aneurysm secondary to pseudocyst erosion of artery. (Reproduced with permission from Stanley JC, Frey CF, Miller TA, et al. Major arterial hemorrhage: a complication of pancreatic pseudocysts and chronic pancreatitis. *Arch Surg* 1976;111:435–440.)

gastroduodenal artery aneurysms (Fig. 93.30) represent an additional 1.5% of these aneurysms. Men are four times more likely than women to develop these lesions. Most patients with these aneurysms are older than age 50 years. Most of these lesions are associated with pancreatitis-related vascular necrosis or vessel erosion by an adjacent pancreatic pseudocyst. Medial degeneration and trauma are less common causes of these aneurysms. Arteriosclerosis is invariably a secondary, not a causative, process. Many recently reported aneurysms have been associated with celiac artery stenoses or occlusions,

FIGURE 93.30. Gastroduodenal artery aneurysm. **A:** Selective celiac arteriogram. **B:** Computed tomography scan of a pancreatic pseudocyst (short arrow) containing the aneurysm (long arrow). (Reproduced with permission from Eckhauser FE, Stanley JC, Zelenock GB, et al. Gastroduodenal and pancreaticoduodenal artery aneurysms: a complication of pancreatitis causing spontaneous gastrointestinal hemorrhage. *Surgery* 1980;88:335–344.)

and likely represent the effect of inordinately high-volume blood flow on branchings of the collateral circulation,^{147,148} where preexisting discontinuities of elastin are known to exist in normal arteries. A similar scenario contributing to aneurysm formation may exist in instances of an SMA occlusion or severe stenosis.¹⁴⁹

Pancreatitis-related aneurysms are often difficult to diagnose and treat. Most are associated with epigastric pain and discomfort, which may be caused by the underlying pancreatic inflammatory disease that accompanies about 60% of gastroduodenal and 30% of pancreaticoduodenal artery aneurysms. Arteriography usually establishes the presence of these aneurysms, but CT scanning and MRI are of increasing importance in their recognition. These latter noninvasive studies are especially important in detecting rupture or associated pancreatic pathology.

Gastroduodenal and pancreaticoduodenal aneurysm rupture has affected more than 50% of the reported cases, occurring in 75% of inflammatory and 50% of noninflammatory lesions. Hemorrhage usually occurs into the stomach, biliary tract, or pancreatic ductal system. Bleeding of pancreatitis-related aneurysms into the peritoneal cavity is less likely, affecting approximately 15% of cases. The overall mortality rate with rupture, including pancreatitis-related aneurysms, approaches 25% despite operative intervention, but is nearly double that figure in the case of true pancreaticoduodenal artery aneurysms.

Surgical intervention is appropriate in all but the poorest-risk patients with gastroduodenal, pancreaticoduodenal, or pancreatic arterial aneurysms.^{63,150-154} Pancreatitis-related false aneurysms are usually treated by arterial ligation from within the aneurysmal sac, rather than extra-aneurysmal arterial ligation. Extensive dissection of the pancreas affected by dense inflammatory adhesions in such circumstances is hazardous. In situations in which a pancreatic pseudocyst or abscess has eroded the artery, a drainage procedure should be undertaken. Distal pancreatectomy, or even pancreaticoduodenectomy, may be the safest mode of treatment in select cases.

9 Transcatheter embolization with coils¹⁵⁵ and glue¹⁵⁶ and electrocoagulation have an important role in treating very high-risk patients.¹⁵⁷⁻¹⁶¹ Thrombin injection may serve as another means of occluding small aneurysms.¹⁶²⁻¹⁶⁵ Nevertheless, rebleeding and late aneurysmal rupture with these therapies can occur and restrict their universal use.^{150,163,165} In select patients, however, endovascular occlusion of the bleeding aneurysm may be an appropriate lifesaving measure, followed by a later definitive open resection.

CHAPTER 94 ■ AORTOILIAC DISEASE

DANIEL J. REDDY, MITCHELL R. WEAVER, AND ALEXANDER D. SHEPARD

KEY POINTS

- 1 Atherosclerotic occlusive disease of the aorta and iliac arteries is one of the most common problems encountered by surgeons.
- 2 The aortic bifurcation is the location where the earliest atherosclerotic changes are first noted in young adults.
- 3 Risk factors for aortoiliac occlusive disease are those for atherosclerosis in general: smoking, hypertension, lipid abnormalities, diabetes mellitus, male sex, older age, and genetic predisposition.
- 4 Smoking appears to be a particularly important risk factor for the development of lower extremity atherosclerotic occlusive disease.
- 5 Claudication is the most common presenting symptom of patients with significant aortoiliac disease.
- 6 Physical examination typically reveals diminished or absent femoral pulses in patients with aortoiliac occlusive disease.
- 7 In the majority of cases, a diagnosis of significant aortoiliac occlusive disease can be made on the basis of the history and physical examination alone.
- 8 Since the very first transarterial dilation procedures, percutaneous transluminal angioplasty has become a commonly performed and, in some cases, the preferred therapy for iliac artery occlusive disease.
- 9 A combined open operation with endovascular surgery appears to have promising results in the treatment of aortoiliac occlusive disease.
- 10 Aortofemoral bypass is the most durable and reliable of all treatment options, for which reason it is the reference standard for the reconstruction of advanced aortoiliac occlusive disease.

- 1 Atherosclerotic occlusive disease of the aorta and iliac arteries is one of the most common problems encountered by vascular surgeons. Alone or in combination with femoropopliteal or tibial occlusive disease, it is the most frequent cause of chronic lower extremity arterial insufficiency. Because a greater number of muscle groups are affected by aortoiliac atherosclerosis than by infrainguinal disease, the resulting symptoms may be particularly disabling. The treatment of symptomatic aortoiliac disease also represents one of the major success stories of modern vascular surgery. Since the first reconstructive procedures on the abdominal aorta were performed nearly five decades ago, treatment has undergone significant progress. Advances in noninvasive vascular diagnosis, arteriography, preoperative assessment, anesthesia, and critical care, in addition to those in surgical technique, have contributed to improved outcomes. The wide availability of magnetic resonance angiography (MRA) and multidetector computed tomography angiography (MDCTA) have facilitated even greater and earlier interventions for a variety of clinical presentations of occlusive aortoiliac arterial conditions. Endovascular and reconstructive procedures for aortoiliac disease have become routine, with low perioperative morbidity and mortality and excellent early and long-term outcomes. The excellent durability of such reconstructions is undoubtedly in large part related to the large caliber and high flow rates of the vessels involved. In recent years, endovascular methods have been added with both increasing frequency and success. This fact has broadened the scope of lesions treated and the patients' ability to undergo treatment with minimal morbidity and time lost from work and family life.

Depending on the pattern of the occlusive process and patient risk, a variety of revascularization techniques are currently available. Selection of a patient-specific treatment strategy from an increasing array of alternatives, although challenging, frequently will alleviate symptoms, avoid an amputation, and prevent or reverse organ dysfunction.

ANATOMY

The arteries supplying blood to the lower extremities are frequently divided into abdominal, or “inflow,” arteries (the aorta and iliac arteries) and infrainguinal, or “outflow,” arteries (the femoropopliteal and tibial arteries). The aorta enters the abdomen from the chest through the aortic hiatus, located between the 12th thoracic and first lumbar vertebrae, and ends at the level of the fourth lumbar vertebra, where it bifurcates into the right and left common iliac arteries. This terminal bifurcation roughly corresponds to the level of the umbilicus. Each common iliac artery curves posteriorly into the sacral hollow and divides into an internal and an external iliac branch. The external iliac artery then curves anteriorly and continues along the psoas muscle under the inguinal ligament to become the common femoral artery, which in turn bifurcates into the superficial and deep (profunda) femoral arteries. The internal iliac (hypogastric) artery follows the curve of the pelvic side wall and branches repeatedly to supply the pelvic viscera and gluteal musculature (Fig. 94.1).

The branches of the abdominal aorta can be divided into three groups:

1. Three unpaired arteries to the gut arise from its anterior wall; the celiac trunk supplies the foregut, the superior mesenteric artery supplies the midgut, and the inferior mesenteric artery perfuses the hindgut.
2. Arteries to the three paired genitourinary glands arise close together from the lateral wall of the aorta—the adrenal, renal, and gonadal branches.
3. Branches to the “roof” and walls of the abdominal cavity include the phrenic, lumbar, and median sacral arteries. These branches assume varying degrees of importance in the formation of collateral perfusion channels around occlusive lesions in the aorta and iliac arteries.

Because the abdominal aorta and its iliac branches are retroperitoneal structures coursing through the deepest portions

FIGURE 94.1. Anatomy of the abdominal aorta and iliac arteries.

of the abdominal cavity, a sophisticated operative technique is required to directly expose them. The proximal (suprarenal) abdominal aorta is rendered particularly inaccessible by the overlying stomach, pancreas, and colon. Occlusive lesions of this portion of the aorta are relatively uncommon, however, in comparison with those of the distal (infrarenal) aorta. The crossing left renal vein serves as a useful surgical landmark defining the usual boundary between these two segments of the abdominal aorta. Although transabdominal exposure of the infrarenal aorta is fairly routine, it requires reflection of the transverse colon superiorly and of the small bowel and its mesentery and distal duodenum to the right. The iliac bifurcations can also be difficult to expose because of their location deep in the pelvis; in addition, the bifurcation of the left iliac artery lies directly behind the sigmoid colon. When appropriate, indirect exposure with images derived from angiography or ultrasound alone may be sufficient to accomplish reconstruction percutaneously or through a remotely placed minimal incision.

PATHOPHYSIOLOGY

Although atherosclerosis is a generalized disease, the earliest and most severe lesions tend to occur at arterial bifurcations and in areas of relative fixation, where the disruption of normal laminar flow is greatest. The aortic bifurcation is in fact the location where the earliest atherosclerotic changes are first noted in young adults. In persons predisposed to the development of more advanced disease, plaque gradually extends proximally into the infrarenal aorta and distally into the common iliac arteries, usually along the posterior wall first. With progressive worsening of the occlusive process, hemodynamic alterations lead to the enlargement of a network of auxiliary or collateral channels around the involved segments. Important collateral arterial pathways around the aortic bifurcation

and common iliac segments are the intercostal and lumbar arteries to circumflex iliac and iliolumbar arteries, the superior to inferior epigastric arteries, and the superior and inferior mesenteric arteries to rectal and internal pudendal arteries. Collateral pathways around occlusive lesions of the external iliac arteries include the hypogastric to circumflex femoral channels (Figs. 94.2 and 94.3).

With slowly developing occlusive lesions, this collateral network is usually sufficient to provide enough blood flow to meet the resting metabolic needs of the lower extremities. These channels, however, do not have the capacity to increase blood flow to the levels necessary to meet the exercise demands of the leg musculature. *Claudication* (from the Latin verb *claudicare*, “to limp”) is the term used to denote the characteristic exercise-induced, cramping pain in the muscles of the lower extremity that results. With acute arterial occlusions and multiple-level disease (occlusive disease in both the aortoiliac and infrainguinal segments), collateral pathways may be inadequate to meet even the basal metabolic needs of nonexercising tissue. The outcome is critical limb ischemia associated with pain at rest, tissue loss (gangrene, nonhealing ulceration), and threatened limb viability.

PRESENTATION

- 2 Although atherosclerosis is a generalized disease, the earliest and most severe lesions tend to occur at arterial bifurcations and in areas of relative fixation, where the disruption of normal laminar flow is greatest. The aortic bifurcation is in fact the location where the earliest atherosclerotic changes are first noted in young adults. In persons predisposed to the development of more advanced disease, plaque gradually extends proximally into the infrarenal aorta and distally into the common iliac arteries, usually along the posterior wall first. With progressive worsening of the occlusive process, hemodynamic alterations lead to the enlargement of a network of auxiliary or collateral channels around the involved segments. Important collateral arterial pathways around the aortic bifurcation
- 3 Risk factors for aortoiliac occlusive disease are those for atherosclerosis in general—smoking, hypertension, lipid abnormalities, diabetes mellitus, male sex, older age, and genetic predisposition. Smoking appears to be a particularly important risk factor for the development of lower extremity atherosclerotic occlusive disease.¹ Patients with symptoms of aortoiliac occlusive disease usually present in their 50s and 60s, whereas patients with symptoms of infrainguinal disease are generally in their 70s.² Patients with critical limb ischemia secondary to multiple-level disease are also generally in this older

FIGURE 94.2. Major pathways of parietal–visceral collateral circulation in aortoiliac occlusive disease.

FIGURE 94.3. Major visceral collateral network available to compensate for occlusive aortoiliac disease.

FIGURE 94.4. Clinical manifestations of critical limb ischemia. A: Patient with ischemic rest pain. Note the absence of hair on the atrophic shiny skin of the feet and the rubor at dependency. B: First-toe ischemia and dermal discoloration of blue-toe syndrome. C: Ischemic ulceration. D: Digital gangrene.

age group. The differential diagnosis includes spinal stenosis, hip arthritis, and nerve root compression.

5 Claudication is the most common presenting symptom of patients with significant aortoiliac disease. Induced by ambulation and quickly relieved by rest, claudication is usually described as a cramping pain, tiredness, or easy fatigability of the involved muscle groups. Although patients with aortoiliac disease classically present with claudication of the thighs, hips, and buttocks, a significant minority may complain of only calf claudication. Erectile dysfunction in men secondary to reduced hypogastric perfusion is another common complaint. The combination of bilateral lower extremity claudication, atrophy of the leg muscles, impotence, and diminished or absent femoral pulses is known as *Leriche syndrome*, after the French physician who first described these classic manifestations of aortoiliac disease.³ Critical limb ischemia associated with rest pain or tissue loss may be a manifestation of aortoiliac occlusive disease, but almost always occurs in combination with more distal femoropopliteal disease (Fig. 94.4). In the absence of infrainguinal disease, aortoiliac collaterals are almost always able to maintain adequate resting tissue perfusion. An exception to this rule is atheroembolic disease, or “blue toe” syndrome. Degenerative plaque(s) in the aortoiliac (or any proximal arterial) segment can ulcerate or rupture to release platelet microthrombi and atheromatous debris into the arterial lumen. Downstream embolization into the microcirculation of the lower extremities can produce digital ischemia and gangrene and dermal discoloration in a characteristic reticular pattern (*livedo reticularis*) (Fig. 94.4). Such patients usually have palpable pedal pulses.

6 Physical examination typically reveals diminished or absent femoral pulses. Severely diseased, calcified femoral arteries may be palpable as firm, tubular masses. Normal femoral and distal pulses may be palpable, however, even in the presence of hemodynamically significant aortoiliac stenoses. Such pulses rapidly disappear following ambulation as the increased flow demands of the exercising leg muscles lead to lowered peripheral vascular resistance. Bruits heard over the lower abdomen or groins suggest the presence of turbulent flow resulting from occlusive plaque. Patients with longstanding aortoiliac atherosclerosis may have disuse atrophy of the lower extremity musculature. Other common signs of lower extremity arterial occlusive disease include trophic changes, such as hair loss on the legs or toes and thin, shiny skin on the feet, in addition to rubor on limb dependency coupled with pallor on elevation. Such chronic advanced changes in addition to gangrene and nonhealing ulceration(s) are unusual in the absence of multiple-level disease.

Classically, different patterns of aortoiliac disease have been identified on preoperative arteriographic studies (Fig. 94.5).⁴ Disease confined to the distal infrarenal aorta and common iliac arteries, classified as type I, accounts for only 10% of patients with inflow disease. Patients with type I disease are younger and more frequently female than patients with other forms of aortoiliac disease, and they usually present with complaints of disabling claudication in the buttocks, hips, and thighs.⁵ Such localized disease may be amenable to endarterectomy or percutaneous transluminal angioplasty. More extensive disease is the rule; atherosclerotic plaque extends distally into the external iliac artery and not infrequently to the common femoral bifurcation in more than 80% of patients. In somewhat less than half this group, no significant occlusive disease is present in the femoropopliteal and tibial segments (type II disease) (Fig. 94.6). Such patients experience worse claudication than persons with more localized, type I disease. In the remaining patients, occlusive disease in the aortoiliac segment is combined with femoropopliteal or tibial disease (type III disease) (Fig. 94.7). As outlined previously, patients with such multiple-level disease are usually older than those in the other two groups and more frequently present with symptoms of critical limb ischemia.

In all groups, the atherosclerotic process progresses unpredictably, but the end result in a small percentage of patients (approximately 5% to 6% in our experience) is occlusion of the terminal infrarenal aorta with propagation of clot proximally to the levels of the renal arteries (Figs. 94.8 and 94.9). In the absence of significant renal artery stenoses, propagation proximally to the renal arteries is an unusual event. One other pattern worthy of mention is aortoiliac hypoplasia, an uncommon variant usually encountered in young to middle-aged women who smoke cigarettes. The infrarenal aorta and iliac arteries are unusually small in caliber and hence prone to significant narrowing, even with modest disease. Operative treatment in such patients can be particularly challenging.

In response to the evolving pattern of aortoiliac occlusive disease (AIOD) treatment, namely, the prominent role of endovascular methods, the Inter-Society Consensus for the Management of PAD (peripheral arterial disease) (TASC II) has reclassified AIOD into four types, A through D⁶:

- Type A: Limited stenoses of the common or external iliac arteries
- Type B: Short stenosis of the infrarenal aorta and short stenosis or occlusion of the iliac arteries
- Type C: Advanced stenosis and/or occlusions of the iliac arteries, especially when calcified
- Type D: Infrarenal aortic occlusion sometimes with multiple iliac occlusions and stenoses

FIGURE 94.5. Common sites of arteriosclerotic lesions in aortoiliac femoral occlusive disease. Although often a generalized process, partially segmental distribution of major disease, most prominent at arterial bifurcations, usually allows surgical revascularization.

FIGURE 94.6. Abdominal aortograms demonstrating type II disease. **A:** Left common and external iliac occlusion can be seen, with reconstitution of the ipsilateral internal iliac and common femoral arteries through visceral and lumbar collaterals. **B:** The right external iliac artery is also occluded, and the right common femoral artery is reconstituted through right hypogastric-to-circumflex femoral channels.

- 7** The value of this and other classifications derives from its power as a template for reporting standards. Stratification of the severity and pattern of the AIOD treated measured by the matching outcomes serves to identify appropriate treatment modalities in individual patients. To simplify, the surgeon could apply endovascular treatment methods for types A and B patients and lean toward open treatment for types C and D. Nonetheless, the velocity of change in endovascular devices and their successful application has weakened the value of any classification owing to the fact that confounding variables cannot, then, be anticipated or controlled. Therefore, the vascular specialist must be conversant and expert with all methods and offer a recommendation based on evaluation, risk assessment, and preference of the individual informed patient.

EVALUATION

In the majority of cases, a diagnosis of significant aortoiliac occlusive disease can be made on the basis of the history and physical examination alone. A clinical diagnosis can and

FIGURE 94.7. Abdominal aortograms demonstrating type III disease. **A:** Extensive atherosclerotic disease has produced both ulcerated plaques and aneurysmal degeneration in the aorta and common iliac arteries bilaterally. **B:** Preocclusive stenoses in the proximal right external and internal iliac arteries and in the left internal iliac artery. **C:** Lateral aortogram highlights the aneurysmal degeneration of the aorta.

should be supplemented by noninvasive vascular testing. Such testing provides valuable information to the treating clinician by confirming the presence of disease and objectively documenting the degree of ischemia and the arterial segment(s) involved. A baseline is established according to which the patient can be followed and interventions planned. Treatment results can be assessed by repeated testing. Such information is particularly useful in a patient with an equivocal history or pulse examination. Arteriography, MRA, and CTA may then be reserved for those patients considered suitable candidates for operative or endovascular (catheter-based) intervention.

Segmental Pressure Measurements

Measurement of the systolic arterial pressures at different levels of the lower extremity with a hand-held, pencil-sized, continuous wave Doppler flow probe is the simplest and most useful noninvasive method to assess arterial occlusive disease. The ratio of the ankle systolic pressure to the brachial systolic pressure is the ankle-brachial index (ABI), or pressure ratio, and is a good indicator of the degree of ischemia present. With the Doppler probe used as an ultrasonic stethoscope, the

FIGURE 94.8. **A, B:** Abdominal aortograms demonstrating juxtarenal aortic occlusion and an extensive collateral network reconstituting the femoral arterial segments. IC, intercostal; ILC, iliac circumflex; IMA, inferior mesenteric artery; LC, left colic; MM, meandering mesenteric; SBC, subcostal; SMA, superior mesenteric artery.

FIGURE 94.9. Pelvic aortogram showing a large collateral from the left hypogastric artery to left profunda artery.

systolic pressures in the dorsalis pedis and posterior tibial artery are measured at the ankle, and each of these values is then the numerator of a simple fraction in which the higher of the two brachial pressures is the denominator. Normal ABIs are generally equal to or slightly greater than 1. Patients with claudication usually have ABIs ranging from 0.5 to 0.9, whereas patients with rest pain and tissue loss have ABIs of less than 0.5.

Determination of limb systolic pressures at different locations (with the “four-cuff” technique, pressures are measured at the upper thigh, lower thigh, calf, and ankle) provides information about which arterial segments are involved with occlusive disease (Figs. 94.10 and 94.11). A pressure drop of more than 20 mm Hg between consecutive levels is indicative of significant disease within the intervening arterial segment. A reduced upper thigh pressure signifies occlusive disease in the aortoiliac or common femoral segments.

In patients with extensive calcification in the walls of the tibial arteries (as is frequently seen in diabetes mellitus or end-stage renal disease), the ankle pressures may not be interpretable because the vessels are too “stiff” to be compressed by the externally applied cuff. In this situation, the pressure in the digital arteries of the great toe can be measured because these small vessels are generally spared calcification. A toe pressure of less than 30 mm Hg indicates severe ischemia. Inspection of the Doppler-derived arterial waveforms can provide additional information when tibial vessels are incompressible.

Patients with claudication occasionally have a normal or nearly normal ABI. As described previously, in such cases the arterial stenosis is not severe enough to cause a pressure drop while the limb is at rest, but does produce a hemodynamic effect under conditions of higher rates of flow, as during exercise. Higher rates of flow through a moderately stenotic segment increase the energy lost at the site, so that a significant distal pressure drop results. Exercise stress testing can be used to evaluate patients suspected of having such disease. ABIs are measured before and after a treadmill exercise protocol; a drop of 15% or more in the ABI following exercise is indicative of hemodynamically significant occlusive disease.

Duplex Scanning

Duplex scanning of the aorta and iliac arteries has been advocated by some as a more precise noninvasive diagnostic tool.⁷ Some authorities have even suggested that duplex scanning can be used to plan therapeutic interventions without the need

FIGURE 94.10. Noninvasive testing to evaluate lower extremity ischemia. **A:** Segmental pressure measurements with cuffs placed at the upper thigh, lower thigh, calf, and ankle. **B:** Stress testing with treadmill ergometry.

FIGURE 94.11. Segmental pressure measurements typical of normal results (A) and aortoiliac occlusive disease (B).

for arteriography. Imaging of the abdominal arteries, however, is difficult because of their deep retroperitoneal and pelvic locations. Many patients are not candidates for such studies because of body habitus and overlying bowel gas; even in experienced hands, this procedure is time consuming. These problems have limited the widespread use of this modality.

DIFFERENTIAL DIAGNOSIS

The diagnosis of aortoiliac disease is usually straightforward, but occasional diagnostic confusion may arise when other causes of lower extremity pain are present. Irritation of lumbosacral nerve roots by spinal stenosis or intervertebral disc herniation may cause buttock and leg pain that is associated with activity. Such symptoms (neurogenic claudication), however, usually cannot be reproduced at the same level of activity and frequently occur when the patient is standing, so that the patient must sit or lie down to obtain relief. In addition, the pain is usually in a classic sciatic distribution. Degenerative arthritis of the hip joints may produce similar buttock, hip, and referred thigh pain. Physical examination typically reveals pain directly over the hip joint that is exacerbated by movement of the joint. Peripheral neuropathy, particularly that associated with diabetes mellitus, may masquerade as ischemic rest pain. In all these situations, segmental limb pressure measurements, with or without stress testing, can be helpful in determining the contribution of arterial occlusive disease to the patient's symptoms.

TREATMENT

The aims of therapy in aortoiliac occlusive disease are to relieve symptoms and, in cases of critical limb ischemia, prevent limb loss (Algorithm 94.1). Medical therapy should be instituted in all patients with symptomatic disease, but is

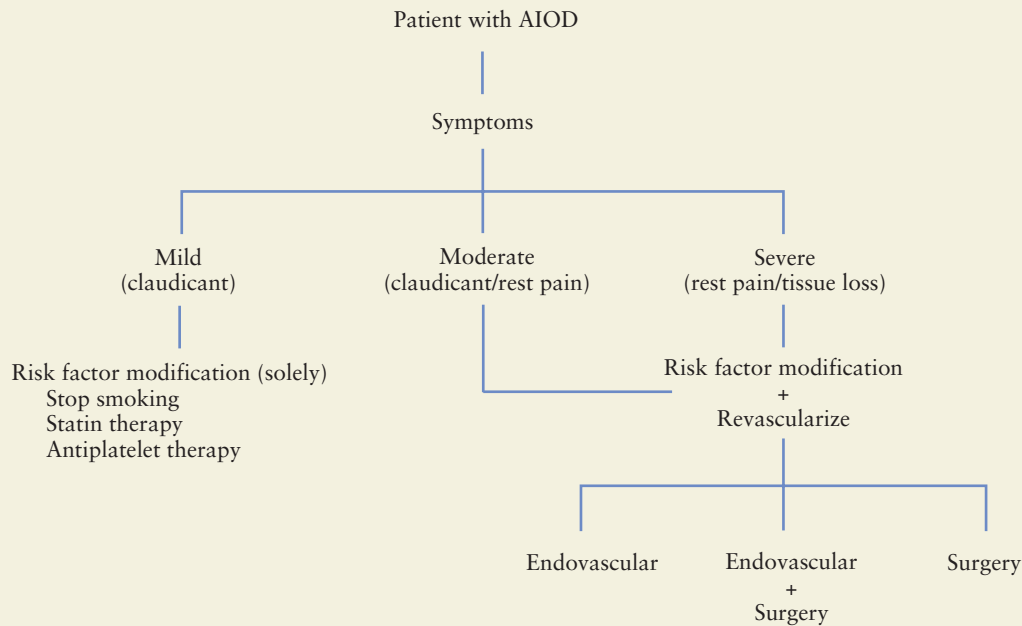

insufficient as sole therapy in patients with limb-threatening ischemia.

Medical Therapy

Risk factor modification, including smoking cessation and the follow-up and treatment of diabetes mellitus, systemic arterial hypertension, and hyperlipidemia, should be an important component of primary care for all these patients.⁸ Although control of these factors will not reverse the atherosclerotic process, it may limit the progression of disease. Furthermore, some data indicate that smoking cessation lessens the severity of symptoms in many patients. Also, a daily exercise program of regular walking may improve collateral development and increase the anaerobic tolerance of ischemic skeletal muscle. Finally, pharmacotherapy with medications, such as pentoxifylline and cilostazol, can be a valuable adjunct in selected patients.^{9,10} Although the mechanisms of action of these agents are unclear, both have effected a modest but significant reduction in claudication symptoms in controlled trials. Some form of platelet inhibition, usually with aspirin, should also be considered for all patients. Although no specific data have demonstrated that antiplatelet therapy is helpful in the treatment of lower extremity arterial occlusive disease, abundant evidence has shown it to be beneficial in the treatment of atherosclerotic occlusive disease in other vascular territories (e.g., coronary and cerebral vessels).

Revascularization

Indications. Revascularization is clearly indicated in patients with critical limb ischemia; without intervention, the vast majority progress to limb loss in a fairly short period of time. Patients with significant or repetitive atheroembolism from an aortoiliac source represent another group who clearly

ALGORITHM 94.1

ALGORITHM 94.1. Management of aortoiliac disease.

benefit from operative therapy. Removal or bypass of the culprit lesion(s) eliminates the risk for further macroembolism and microembolism. The treatment for patients with claudication secondary to aortoiliac occlusive disease remains somewhat controversial and must be individualized. Patients with mild to moderate symptoms can be treated medically with satisfactory results. Patients with severe, disabling, lifestyle-limiting symptoms of claudication can benefit from revascularization therapy. The current safety and long-term durability of direct aortic reconstruction make this approach acceptable even for older, higher-risk patients with significant symptoms. For patients who cannot tolerate such procedures, a variety of other methods of revascularization are available that have had good long-term success rates.

Arteriography and Computed Tomography Angiography

Once a decision has been made to proceed with revascularization therapy, contrast digital subtraction arteriography is used for a detailed anatomic evaluation of the arterial circulation of the lower extremities. Such information is necessary to choose the most appropriate method of revascularization (operative or endovascular) and plan the procedure. Biplane abdominal aortography with demonstration of the arterial tree below the inguinal ligament ("runoff") is required. This procedure is most commonly performed from the femoral artery with the best pulse by means of a retrograde Seldinger technique. When neither femoral artery is available, a transaxillary or translumbar approach provides good access. Anteroposterior views of the aortoiliac segments demonstrate the extent of the occlusive process and the pattern of collateral formation. Oblique views of the iliac and femoral arteries are frequently

necessary to document posterior wall plaque and stenoses at the origins of the deep femoral arteries. Lateral aortography provides information about the origins of the visceral arteries, whereas anteroposterior views demonstrate the renal arteries. Views of the runoff to at least the midcalf level are required to assess the degree of associated occlusive disease; in cases of critical limb ischemia, visualization of the pedal circulation is usually necessary. CTA with reformatting also requires the administration of contrast. However, it may be administered intervenously. Access to and familiarity with sophisticated computer-based protocols is required for both image acquisition and postprocessing reformatting when CTA is the chosen imaging method. One of the added values of CTA is the ability to survey and retrieve a practically limitless array of images, allowing endovascular treatment planning and follow-up.

Occasionally, the hemodynamic effect of a stenosis or series of stenoses along an iliac arterial segment may be difficult to determine, even with oblique views. When the significance of a stenosis remains in question, pressures proximal and distal to the lesion(s) can be measured. A systolic drop of more than 5 to 10 mm Hg across the stenosis is indicative of a hemodynamically significant lesion. For borderline cases, distal pressure measurements can be obtained before and after interarterial injection of a vasodilator to simulate the hyperemic hemodynamics of exercise. A pressure drop of 20 mm Hg or more during hyperdynamic flow is considered to indicate hemodynamic significance.

The information supplied by arteriography is crucial to the success of a revascularization procedure. In addition to providing a detailed "road map" of the exact arterial segments involved and the pathology present, arteriography identifies associated anatomic variations (e.g., accessory renal arteries) and aortic wall characteristics (e.g., extensive calcification, ulcerated plaque), which may alter the operative approach and

the conduct of the procedure. For example, an operating surgeon who knows that the aortic wall just below the renal arteries is heavily diseased with ulcerated plaque may decide to control the aorta at a more proximal level rather than risk dislodging atheromatous debris with standard infrarenal aortic clamping. Similarly, documented occlusive lesions in the visceral or renal arteries (e.g., a patent inferior mesenteric artery with a large “meandering mesenteric artery”) may best be addressed at the time of aortic reconstruction or require particular attention to avoid complications.

The major risks of arteriography, allergic reactions and contrast-induced renal dysfunction have been greatly reduced during the last several years by the introduction of newer non-ionic contrast agents and recognition of the importance of adequate hydration before the procedure. Nevertheless, interest has been increasing in the use of magnetic resonance imaging (MRI) to avoid some of these complications of angiography. MRA technology does not always provide sufficient image detail or accuracy to supplant traditional angiography in the evaluation of aortoiliac occlusive disease.¹¹ Once considered appropriate, MRA in patients with moderately severe renal dysfunction (glomerular filtration rate <60 mL/min/1.72 m²), for whom the burden of radioactive contrast in a complete aortogram with runoff study is considered too risky, is now being questioned owing to the recognition of a unique pattern of inflammatory systemic and nephrotoxic risks associated with administration of paramagnetic agents in a small number of patients.

Choice of Revascularization Technique

A variety of surgical procedures, both endovascular and open, are available for revascularization of the patient with aortoiliac occlusive disease. Selection depends on a number of factors, including the pattern of the occlusive process, patient risk, and surgeon experience. Commonly used techniques include (a) catheter-based balloon dilation, with or without luminal stenting; (b) aortoiliac endarterectomy; (c) arterial reconstruction with an anatomically placed bypass prosthesis (aortofemoral or iliofemoral); and (d) arterial reconstruction with a remote or extra-anatomically placed bypass prosthesis (axillofemoral or bifemoral, femorofemoral, thoracofemoral). Catheter-based techniques are best suited for focal lesions of the common iliac arteries. Endarterectomy is limited to good-risk patients with focal occlusive disease at the aortic bifurcation and common iliac arteries. Prosthetic aortobifemoral bypass is the procedure of choice for most patients with advanced, extensive aortoiliac involvement and is considered the “gold standard” technique for aortoiliac revascularization. Axillofemoral or bifemoral bypass is reserved for the small subpopulation of patients in whom standard direct aortic reconstruction is considered too risky, either for medical reasons (usually severe pulmonary or cardiac disease) or technical reasons (aortic reoperations, multiple prior abdominal procedures with dense adhesions, prior abdominal irradiation, prosthetic graft infections). The descending thoracic aorta can be considered as an alternative arterial source for the construction of a thoracofemoral bypass in good-risk patients with a “hostile” abdomen.¹² Femorofemoral or iliofemoral bypass can be used in poor-risk patients with diffuse unilateral iliac disease or bilateral iliac involvement when the stenosis in one of the iliac arteries can be appropriately treated by balloon angioplasty, with or without intraluminal stenting.

Preoperative Evaluation

The evaluation of patients for whom aortoiliac reconstruction is being considered should include a careful assessment of overall operative risk. Age per se is not a contraindication to a

standard direct aortic reconstruction, if it is needed. A “lesser” procedure of more limited durability, however, may provide a similarly excellent outcome in a patient with reduced life expectancy. Patients with significant aortoiliac disease may have atherosclerotic occlusive disease in other vascular territories (e.g., coronary, cerebral) that affects their operative risk. The detection and treatment of significant coronary artery disease is particularly important because myocardial infarction is the leading cause of both perioperative and late mortality.¹³ More than 50% of patients with aortoiliac occlusive disease have clinical or electrocardiographic evidence of coronary disease.¹³ Selected patients may require cardiac catheterization and even occasional coronary angioplasty or bypass grafting before undergoing aortic reconstruction.¹⁴ Pulmonary and renal function should also be routinely assessed because of the higher mortality associated with postoperative dysfunction of these organ systems.

Endovascular Treatment

8 Since the very first transarterial dilation procedures, percutaneous transluminal angioplasty (PTA) has become the most commonly performed and, in some cases, the preferred therapy for iliac artery occlusive disease.²⁰ Like operative reconstruction, PTA when properly selected in this anatomic segment is likely to be successful owing to the large caliber of the vessels and high rates of flow in the aortoiliac segment. Acceptance of endovascular treatment by surgeons and patients for aortoiliac disease continues to advance at a rapid pace. Many factors must be taken into consideration before selecting aortoiliac angioplasty or stent placement for the treatment of aortoiliac occlusive disease. The continuum from claudication to limb-threatening ischemia, and patient comorbidities are primary considerations. Usually patients with mild to moderate aortoiliac disease are easily amenable to angioplasty or stent. The best results are obtained with short, focal, nonocclusive lesions in the common iliac arteries.¹⁵ Patients with severe atherosclerotic lesions, long (>10 cm) and complex aortoiliac stenosis, or occlusions would benefit from revascularization, although many anecdotes illustrate short-term success with endovascular approaches (Fig. 94.12). Complications (thrombosis, dissection, perforation, and distal embolism) in experienced hands are uncommon and can frequently be remedied with intraluminal stenting or thrombolytic therapy. Stents have made it possible to apply angioplasty in a larger number of lesions (e.g., longer occlusions) and may improve long-term patency rates by reducing rates of restenosis.¹⁶ This technique is particularly useful in high-risk patients, those with critical ischemia secondary to multiple-level disease, and patients in whom iliac PTA can be combined with an infrainguinal bypass for limb salvage. Even in good-risk patients with focal iliac disease, however, PTA may be the preferred initial approach, with surgical intervention reserved for the more difficult circumstances following endovascular failures. If the presence of an appropriate lesion is suspected, PTA may be considered at the same time that the diagnostic arteriogram is performed. Open surgery involves an up-front risk in the initial stages, with anesthesia and longer hospital stays. The endovascular model involves the continued surveillance and initial lower up-front risk. These patients will require follow-up angiography and repeat interventions as the disease continues to progress and, ultimately, more investment in time and resources. Complications are usually local. Long-term results depend on the initial extent of aortoiliac disease, but usually will not be as good as open surgery. Results from angioplasty of iliac arteries range from 70% to 90% over a 3-year span. This continues to decrease to as low as 50% patency at 5 years. Iliac artery occlusion with resultant endovascular recanalization shows patency of 70% at 1 year and 60% at 3 years. Nonetheless, the results of endovascular treatment are improving and the

FIGURE 94.12. A: Abdominal aortogram demonstrating bilateral iliac and femoral artery stenosis. B: Bilateral iliac and femoral artery endarterectomies. C: Bilateral common iliac artery stenosis. D: Placement of bilateral common iliac artery stents. E: Digital subtraction view of bilateral common iliac artery stents.

proportion of patients being treated by endovascular methods has increased in recent years. Many vascular specialists now prefer endovascular treatment over open treatment. Open surgery involving an aortobifemoral bypass has been a durable operation for decades. Patency is usually greater than 85% at 5 years. Of course, the prudent vascular specialist is thoroughly conversant with both open and endovascular treatment modes and, ordinarily, will be capable of providing whichever alone or in combination is best for the patient. Clinical follow-up of the patient by the treating vascular specialist is ordinarily routine as well.

- 9 A combined open operation with endovascular surgery appears to have promising results and demonstrates that ideal patient care outcomes remain in the hands of the vascular surgeon (Fig. 94.13). Preliminary results show that infrainguinal

bypass with concomitant aortoiliac angioplasty or stenting, or both, have a slightly higher patency of the distal bypass.¹⁷ With the continued advancement of stents, smaller delivery devices, fluoroscopy equipment, and operator skills, endovascular intervention will continue to be a major component of care of the patient with aortoiliac occlusive disease.

Endarterectomy

Endarterectomy was more commonly performed in the era before prosthetic graft conduits were developed. Currently, direct arterial repair is reserved for the management of focal atheroocclusive disease (type I) limited to the distal aorta and common iliac arteries (Fig. 94.14). When performed for this

FIGURE 94.13. **A:** Initial angiogram revealing significant right iliac system occlusive disease with a chronic total occlusion of the proximal right external iliac artery. **B:** Follow-up digital subtraction arteriogram after percutaneous balloon angioplasty and stenting of right external iliac artery, revealing successful recannulization with a widely patent lumen.

specific indication, aortoiliac endarterectomy can produce excellent long-term results, similar to those of aortofemoral grafting. Endarterectomy is less well suited for disease extending in the external iliac arteries and is to be avoided when aneurysmal degeneration complicates the primary atheroocclusive aortoiliac process.

The aorta and common iliac arteries are exposed and vascular control is secured. During dissection, care is taken to preserve the autonomic nerves overlying the aortic bifurcation so that normal sexual function is not disturbed. The patient is then heparinized and atraumatic occlusion clamps or tapes are applied. Arteriotomies are made over the aorta and the common iliac arteries to expose the diseased lumen. The atherosclerotic plaque, along with the overlying intima and inner portion of the involved media, is removed. Good “breakoff” points for the removed plaques are needed to prevent postop-

erative thrombosis that results from the formation of an occluding flap of retained atheroma. The arteriotomies are closed by direct suture or with patch angioplasty, depending on vessel caliber.

Aortofemoral Prosthesis

- 10 Aortofemoral bypass is the most durable and reliable of all treatment options, for which reason it is the reference standard for the reconstruction of advanced aortoiliac occlusive disease (Figs. 94.15 and 94.16). The operative sequence starts with exposure of the abdominal aortic segment between the renal and inferior mesenteric arteries by means of appropriate retroperitoneal dissection and cephalad mobilization of the fourth portion of the duodenum and

FIGURE 94.14. **A:** Preoperative aortogram demonstrating severe atherosclerosis. **B:** Large amount of plaque removal. **C:** Completion operating room photo of closed, repaired aorta and iliacs.

FIGURE 94.15. A: Preoperative angiogram demonstrates severe stenosis of the infrarenal aorta with mild stenosis bilaterally at the origin of the common iliac arteries (type I disease). B: Long arteriotomy over the infrarenal aorta and proximal right common iliac artery reveals advanced ulcerated luminal disease. A second, separate arteriotomy over the left common iliac artery was also created to approach plaque in that vessel. C: Aortic component of the atherosclerotic plaque. D: The two arteriotomies are closed, and polytetrafluoroethylene patches are used for angioplasty.

the left renal vein. Care is taken during dissection to avoid injury to the lumbar veins. Moreover, gentle handling of the dissected segment may lessen the risk for atheroembolism during the operation. The common, superficial, and deep femoral arteries are secured through separate groin incisions. Retroperitoneal tunnels are then developed between the exposed infrarenal aorta and the groins by means of blunt dissection. Care is taken to avoid injury to the bowel, particularly the rectosigmoid on the left. The tunnels are directed posterior to the ureter to avoid postoperative obstructive uropathy from graft limb compression of the ureter. A prosthesis of the appropriate size (polytetrafluoroethylene or Dacron) is selected, and the patient is heparinized. With an occluding clamp below the renal arteries and another just above the inferior mesenteric artery, the proximal anastomosis is performed as either an end-to-end or end-to-side graft to the aorta. The end-to-side technique has been found to be just as good, depending on the pattern

of occlusive lesions and opportunity to perfuse the internal iliac arteries. The proximal anastomosis is placed as close to the renal arteries as practical to prevent future compromise of the bypass resulting from progression of atherosclerosis in the remaining infrarenal cuff. The limbs of the prosthesis are then delivered through the retroperitoneal tunnels into the groins. The distal anastomoses are performed to the common femoral arteries and may be carried into the deep femoral arteries as needed. The technique for distal femoral anastomosis is chosen to ensure adequate graft outflow, particularly if superficial femoral artery disease is present. In the patient with tissue loss secondary to type III or multiple-level aortoiliac disease associated with occluded superficial femoral arteries and compromised deep collaterals, concomitant distal reconstruction should rarely be required (Fig. 94.17).

Aortofemoral bypass has excellent 5- and 10-year graft patency rates of approximately 85% and 75%, respectively.

FIGURE 94.16. A, B: Preoperative biplane aortograms demonstrate advanced preocclusive disease of the infrarenal aorta and its bifurcation with occlusion of the left common and external iliac arteries (type II disease). C: The patient was treated with placement of an aortobifemoral prosthesis. The short shaft and limbs of the prosthesis are in a retroperitoneal location and are partially covered with a layer of posterior parietal peritoneum. The two groin incisions are kept open to display the anastomoses of the two limbs to the common femoral arteries.

FIGURE 94.17. A: Preoperative aortogram demonstrates advanced preocclusive disease of the infrarenal aorta and its bifurcation with occlusion of the left common and external iliac arteries (type II disease). B: Aortogram after placement of an aortobifemoral prosthesis.

Perioperative morbidity and mortality are reported to be below 10% and 5%, respectively, in many centers.^{13,18}

Axillofemoral Prosthesis

Axillofemoral extra-anatomic reconstruction has been used for revascularization in poor-risk patients and in those with a hostile abdomen and has been reported to be an acceptable alternative to aortofemoral prosthesis. The axillary artery supplying the arm with the higher systolic blood pressure is usually chosen as the inflow vessel. The operative sequence starts with exposure of the most proximal part of the axillary artery through an infraclavicular incision and splitting of the pectoralis major muscle between its sternal and clavicular heads. The common, superficial, and deep femoral arteries are then dissected through groin incisions. The axillary or long limb of an externally supported polytetrafluoroethylene graft is then advanced behind the pectoralis major muscle and through a subcutaneous tunnel in the anterior axillary line connecting the axillary artery and the ipsilateral groin. Next, a cross-femoral-to-femoral limb of the graft is delivered through a subcutaneous suprapubic tunnel connecting the two groins. An anastomosis between the proximal axillary artery and the prosthesis is constructed in an end-graft-to-side-of-artery fashion. The graft is positioned parallel to the axillary artery and behind the pectoral muscles for the first 10 cm, before it enters the subcutaneous channel along the anterior axillary line. Following this plan seems to minimize traction on the anastomosis during arm movement and reduces the incidence of anastomotic disruption. The distal anastomoses are performed to the common femoral arteries and may be carried over or onto the deep femoral arteries to ensure adequate graft outflow (Fig. 94.18).

FIGURE 94.18. This diabetic patient presented with gangrene of the right first and second toes. A: The preoperative angiogram revealed aortic bifurcation disease, right external iliac and superficial femoral arterial occlusion, and reconstitution of a heavily diseased right deep femoral artery. On the left, occlusion of the superficial femoral artery is seen, with a patent left deep femoral artery supplying the left leg (multiple-level type III disease). B: The patient underwent an aortobifemoral bypass with a concomitant right femoral-to-below-knee popliteal bypass to bring pulsatile flow to the diseased forefoot.

The reported 5-year patency of the axillofemoral graft varies widely (30% to 80%), but is generally accepted to be lower than the patency of an aortofemoral prosthesis. The axillobifemoral bypass should therefore be reserved for patients with bilateral advanced aortoiliac disease who are either poor surgical risks or have a hostile abdomen.¹⁹

Other Prosthetic Reconstructions

For high-risk patients with diffuse advanced disease limited to one iliac artery, unilateral femorofemoral or iliofemoral bypass may be used to revascularize the ischemic extremity. If the contralateral iliac artery is normal or bears a lesion that is well treated by angioplasty or stenting, cross-femoral-to-femoral artery bypass is worthy of consideration. Iliofemoral bypass has a modest graft patency advantage over femorofemoral bypass (70% vs. 60%, respectively), but the main advantage is avoidance of a second groin incision and its associated complications. Femorofemoral bypasses are reserved for patients with occluded or heavily diseased common iliac arteries, in whom iliofemoral bypass is not advisable (Fig. 94.19).

FIGURE 94.19. A unilateral axillary to ipsilateral femoral artery bypass graft is supplemented with a cross-femoral-to-femoral artery bypass graft limb. This extra-anatomic graft is frequently implanted on the right (although the artist's depiction shows the left) to allow unimpeded access to the thoracoabdominal aorta when necessary.

CHAPTER 95 ■ FEMOROPOPLITEAL AND TIBIAL OCCLUSIVE DISEASE

WILLIAM P. ROBINSON, MATTHEW T. MENARD, AND MICHAEL BELKIN

KEY POINTS

- 1 Infrainguinal arterial bypass surgery remains the signature operation distinguishing vascular surgeons from other specialists involved in the treatment of peripheral vascular disease.
- 2 Chronic obliterative atherosclerosis of the infrainguinal vessels is the most prevalent manifestation of arterial occlusive disease encountered by the vascular surgeon.
- 3 The most common lesion seen below the inguinal ligament is that of a short-segment total occlusion of the superficial femoral artery.
- 4 The diagnosis of infrainguinal occlusive disease is generally made based on patient symptomatology, physical examination, and noninvasive tests, such as segmental pressure measurements and pulse volume recordings.
- 5 A particularly virulent form of atherosclerotic arterial disease is often found in young female smokers.
- 6 Typically, half of patients proceeding to surgery for arterial occlusive disease have significant coronary artery disease, even more have hypertension, and almost 80% are current or prior cigarette smokers.
- 7 Percutaneous therapy is often applied as first-line therapy in appropriate patients with more limited extent of anatomic disease and/or high operative risk.
- 8 Open surgical revascularization remains the “gold standard” for those patients with disabling claudication, ischemic rest pain, and ischemic ulceration or gangrene.
- 9 Infrainguinal bypass surgery is best performed with autogenous vein conduit, preferably the ipsilateral greater saphenous vein if available.
- 10 Many of the patients undergoing surgical reconstruction for arterial insufficiency will require one or more adjunctive operative procedures for salvage of their foot.

Arterial occlusive disease is highly prevalent in Western society and constitutes the leading overall cause of death in the United States. With the aging of the American population, the prevalence of lower extremity occlusive disease has steadily increased in recent decades. Not surprisingly, therefore, the clinical manifestations and complications of atherosclerosis are the most common therapeutic challenge encountered and treated by vascular surgeons.

The tendency for atherosclerotic lesions to develop at specific anatomic sites and follow recognizable patterns of progression was first appreciated in the late 1700s by the British anatomist and surgeon John Hunter. Considered one of the forefathers of vascular surgery, his dissections of atherosclerotic aortic bifurcations are preserved at the Hunterian museum in London and presage the disease process that Leriche would give his name to 150 years later.¹ The modern era of surgical reconstruction for complex atherosclerotic occlusive disease began in earnest in 1947, when the Portuguese surgeon J. Cid dos Santos successfully endarterectomized a heavily diseased common femoral artery.² Four years later, building on the pioneering work of Alexis Carrel,³ Kunlin⁴ would report the first long-segment vein bypass in the lower extremity. It would be another 10 years before the initial efforts to extend vein grafting to the tibial level were described by McCaughan.⁵ The last three decades have seen tremendous advances in both the

understanding of atherosclerosis biology and refinement in the techniques of infrainguinal revascularization that greatly improved surgeons' ability to preserve limbs and improve quality of life in patients with femoropopliteal and tibial occlusive disease. In more recent years, advances in percutaneous treatment have revolutionized the treatment of infrainguinal occlusive disease. The concept of intravascular intervention was pioneered in the late 1960s by the radiologist Charles Dotter,⁶ and advanced greatly with the advent of the angioplasty balloon by Gruntzig in the early 1970s.⁷ Nevertheless, endovascular intervention for infrainguinal disease was not utilized significantly until the 1990s. The technology remains in rapid development and surrounded by ongoing controversy as to its proper role.

- 1 Although a diverse range of technical skill is required of the contemporary vascular and endovascular surgeon, it is worth noting that infrainguinal arterial bypass surgery remains the signature operation distinguishing vascular surgeons from other specialists involved in the treatment of peripheral vascular disease. This distinction stems primarily from the fact that the outcome of infrainguinal reconstruction is highly dependent on the judgment and technical skill of the surgeon, with the end result being either successful limb salvage or major limb amputation. This chapter reviews the surgical management of femoropopliteal and tibial arterial occlusive disease

and details standard and advanced techniques underlying successful infrainguinal operative revascularization. It also briefly discusses the emerging role of endovascular surgery in the management of infrainguinal occlusive disease, though a thorough review of these techniques is beyond the scope of the chapter.

INFRAINGUINAL ARTERIAL OCCLUSIVE DISEASE

Epidemiology and Risk Factors

The prevalence of peripheral arterial disease (PAD) is between 3% and 10% overall and 15% and 20% in those over age 70.^{8,9} Symptomatic PAD in the form of claudication affects approximately 10 million Americans, including 1% to 2% of those younger than 50 years, 5% of those ages 50 to 70, and 10% of those older than 70 years.¹⁰ Of those older than 50 years of age with PAD, 1% to 3% will have critical leg ischemia (CLI) in the form of rest pain or gangrene.^{11,12} The incidence of CLI ranges from 220 to 1,000 new cases per year in a European or American population of 1 million people.¹³ The classic risk factors for infrainguinal occlusive disease are the same as those for the development of atherosclerosis in general and include age, male gender, hypertension, diabetes mellitus (DM), smoking, dyslipidemia, family history, and homocysteinemia. The propensity for heavy smokers to develop superficial femoral artery disease and for diabetics to develop tibial disease should be noted. More recent evidence indicates that nonwhite ethnicity, inflammatory markers such as C-reactive protein, and perhaps chronic renal insufficiency (CRI) are also associated with an increased risk of PAD.^{14–16}

Presentation and Natural History

- 2 Chronic obliterative atherosclerosis of the infrainguinal vessels is the most prevalent manifestation of arterial occlusive disease encountered by the vascular surgeon. Patients are classified into two broad categories depending on their symptomatology: claudicants and those with CLI. Claudication, the reproducible ischemic muscle pain resulting from inadequate oxygen delivery during exercise, is the cardinal presenting symptom. Natural history studies indicate patients with claudication have increased rates of cardiovascular mortality, but an overall low risk of limb loss.^{17,18} Seventy to 80% of patients with claudication demonstrate a stable pattern of disease throughout their lifetime or have improvement in their symptoms as a result of risk factor modification, whereas 20% to 30% undergo operation within 5 years as a result of disease progression. Claudication will progress to critical limb ischemia in only 5% to 10% of patients over their lifetime. However, claudication is a marker for increased cardiovascular morbidity and mortality, with 20% of patients experiencing a nonfatal myocardial infarction or stroke and 10% to 15% dying of cardiovascular-related mortality at 5 years.¹² The annual rates of mortality and limb loss in patients with claudication are approximately 2% to 5% and 1%, respectively.^{12,19}
- 3 The most common atherosclerotic disease pattern encountered distal to the inguinal ligament is that of a short-segment total occlusion of the superficial femoral artery. Isolated disease of this nature typically presents as calf muscle claudication. It is not uncommon, however, for patients with significant single-level lesions, even those with long-segment arterial occlusions, in the superficial femoral artery or more distal arterial beds to be only minimally symptomatic or even asymptomatic. While this can sometimes be the result of exercise limitations imposed by concomitant coronary arterial disease or other physiologic impairments such as lung disease or arthri-

tis, it is more often a result of compensatory collateral flow. Collateral perfusion from the profunda femoral artery around a heavily diseased or occluded superficial femoral artery frequently reconstitutes the distal superficial femoral artery or popliteal artery with enough well-perfused arterial blood to ensure sufficient resting tissue perfusion. Similarly, the rich network of geniculate collaterals can sometimes compensate for a diseased popliteal arterial segment to a sufficient degree to prevent rest pain or overt tissue loss, but will usually prove insufficient to meet the increased metabolic demands of ambulation and forestall claudication.

Critical limb ischemia, which must be differentiated from acute limb ischemia, refers to the presence of either rest pain or tissue loss in the lower limb. Rest pain occurs when blood flow is inadequate to meet resting metabolic requirements. In the lower extremity, ischemic rest pain is localized to the foot, frequently in the instep, and should be easily distinguishable from benign muscle cramps in the calf commonly seen in older patients. Patients with rest pain are often awakened by severe discomfort in the forefoot and hang the affected extremity over the edge of the bed for temporary symptomatic relief. Trophic changes, such as muscle wasting, thinning of skin, thickening of nails, and hair loss are frequently also seen in the distal affected limb. Rest pain is an ominous symptom and usually requires revascularization given the tendency for progression to tissue loss. Ischemia ulcerations usually begin as small, dry ulcers of the toes or heel area and progress to frankly gangrenous changes of the forefoot or heel with greater degrees of arterial insufficiency (Fig. 95.1). Patients with diabetes or renal failure are more susceptible to the development of ischemic pedal ulcers. Disease progression can be very rapid, as up to 50% of patients with CLI are asymptomatic 6 months before onset of pain or ulceration.¹⁰ Such progressive disease, affecting multiple levels of the peripheral vasculature tree, is more frequently encountered in the elderly.

The natural history of CLI is dismal as these patients are generally of advanced age and possess significant comorbidities contributing to their advanced limb ischemia. Overall, approximately 25% of patients with CLI will die at 1 year, 30% will undergo major amputation, and 45% will be alive with two limbs.¹² The rate of amputation is 10 times higher in diabetics than nondiabetics and 5- and 10-year mortality in patients with CLI have been reported to be 60% and 85%, respectively.¹⁰ CLI mandates revascularization for limb salvage when feasible as limb salvage with medical therapy and wound care is virtually futile; success rates for rest pain and tissue loss have been reported to be as low as 27% and 5%, respectively.¹⁰

Patients with rest pain or ischemic tissue loss typically manifest more extensive involvement of the femoral, popliteal, or tibial arteries than patients with claudication. Those with tissue loss also more commonly have multilevel disease involving the femoropopliteal system in combination with occlusive disease of the aortoiliac vessels or the infrageniculate runoff.²⁰

Several identifiable patterns of infrainguinal occlusive disease are well recognized. Patients with an extensive history of cigarette smoking typically have lesions limited to the superficial femoral artery and corresponding symptoms of calf claudication (Fig. 95.2). Diabetes, in contrast, most often targets the tibial vessels, and patients may present with frank tissue necrosis in the presence of a palpable popliteal pulse and no prior history of claudication. Alternatively, the so-called “blue toe syndrome” is a situation in which atherosclerotic debris breaks free from a more proximal source, for example, an aortoiliac or femoropopliteal plaque or a thrombus-lined aneurysm, and embolizes to the distal vessels.^{21,22} Wire manipulation during coronary or peripheral angiographic procedures and cross-clamping across a calcific aortic plaque during cardiac surgery are common sources of such emboli. The terminal target of the microembolic particles, whether cholesterol crystals, calcified plaque, thrombus, or platelet aggregates, is typically the small vessels of the toes and heel.

FIGURE 95.1. Examples of digital ischemic ulcerations resulting from progressive arterial insufficiency.

FIGURE 95.2. Long-segment total occlusion of superficial femoral artery in a patient with a long history of cigarette smoking and severe claudication.

- 5 A particularly virulent form of atherosclerotic arterial disease is often found in young female smokers.^{23,24} Radiographic imaging in this subset of patients typically reveals atretic, narrowed vasculature with diffusely calcific atherosclerotic changes. Such patients invariably have an extensive smoking history, with or without other typical risk factors for atherosclerosis. Given the diminutive size of the inflow and outflow vessels, the durability of endovascular intervention is generally inferior in these patients, particularly in the face of continued cigarette use.
- 6 Typically, half of patients proceeding to surgery for arterial occlusive disease have significant coronary artery disease, even more have hypertension, and almost 80% are current or prior cigarette smokers.^{25,26} The low mortality and morbidity associated with operative intervention in recent years is in large part a result of advances in the management of concomitant coronary disease. Specifically, the importance and benefit of better preoperative identification of patients in need of initial coronary revascularization, awareness of the benefit of waiting an interval period following coronary stenting prior to proceeding with major noncoronary vascular surgery, improved perioperative pharmacologic management of patients with impaired myocardium, and more focused efforts to tailor operative and postoperative fluid administration to the individual patient's myocardial reserve are all well recognized.^{27,28} Appropriate beta blockade and the use of statins have been shown to reduce cardiovascular events and improve survival in patients undergoing vascular surgery, including infrainguinal bypass.^{29,30} General advances in postoperative management, including pulmonary care, infection control, and blood product utilization, have further contributed to the progress seen.

Diagnosis

- 4 The diagnosis of infrainguinal occlusive disease is generally based on patient symptomatology, physical examination, and noninvasive tests, such as segmental pressure measurements and pulse volume recordings. Accurate history taking and physical examination are crucial to clarifying the diagnosis and guiding a treatment management aimed at maximizing symptom relief and limb preservation. Intermittent claudication (IC) indicative of infrainguinal occlusive disease is typically a cramping, aching discomfort consistently reproducible at a given distance and relieved soon after cessation of ambulation. This must be differentiated from lower extremity pain secondary to nerve root compression or spinal stenosis, which, in contradistinction to vasculogenic pain, often develops when patients maintain a stationary standing posture. Vasculogenic claudication must also be distinguished from venous claudication, hip and ankle arthritis, symptomatic Baker cyst, and chronic compartment syndrome. IC patients with isolated infrainguinal disease will likely have palpable femoral pulses but diminished popliteal and/or pedal pulses.

As is true with claudication, ischemic rest pain must be carefully distinguished from other sources of pain in the elderly population, most commonly arthralgia and neuropathy. Although tissue necrosis and gangrene are usually self-evident when caused by critical ischemia, similar lesions associated with venous stasis, severe anemia, decubitus ulcers, and diabetic neuropathy must be excluded.

Measurement of the ankle-brachial index (ABI) is frequently a useful diagnostic adjunct. A properly performed ABI in a claudicant without significant evidence for vascular calcification would be expected to be between 0.5 and 0.9. Segmental pressure measurements at the level of the upper thigh, lower thigh, upper calf, ankle, and metatarsal level also aid in localizing the level of hemodynamically significant disease. In patients with diabetes mellitus or CRI leading to extensive vascular calcification, the ABI will often be erroneously elevated due to noncompressibility of the vessels. In such circum-

stances, pulse volume recordings should remain a reliable indicator of perfusion to the various levels of the lower extremity. Measurement of toe pressures also effectively quantitates distal perfusion.

Only after the diagnosis of significant infrainguinal disease and the decision to pursue intervention have been made is further imaging warranted. Duplex ultrasonography, magnetic resonance angiography (MRA), and computed tomographic angiography (CTA) are increasingly being utilized as first-line modalities in planning the optimal revascularization approach, and have supplanted contrast angiography as the initial imaging study of choice in many centers. Nevertheless, due to inherent limitations with each of these techniques, digital subtraction angiography remains the "gold standard" technique for imaging of the vascular tree prior to intervention.

Although a growing literature supports the use of duplex scanning as a standalone preoperative mapping modality,³¹ this use requires a highly dedicated vascular laboratory and to date has not gained wide acceptance. CTA is increasingly being utilized as a preoperative road mapping technique in institutions able to provide high-quality three-dimensional reconstructions. MRA is also particularly useful as a noninvasive screening test to determine the suitability for percutaneous therapy, as advances have solved many of the technical limitations of earlier studies (Fig. 95.3). Should a lesion amenable to percutaneous therapy be identified, angiography is then pursued. Alternatively, in some instances of femoropopliteal reconstruction, operative planning may be based solely on MRA scanning if high-quality time-of-flight and gadolinium-enhanced images are obtained.³²⁻³⁴ In many cases, however, surgeons are reluctant to proceed to surgery without the confirmation afforded by standard contrast angiography. This reluctance is particularly true if the distal target is at the tibial or pedal level, where anatomic detail provided by CTA and MRA remains more limited.

When digital subtraction angiography is undertaken for preoperative planning, a retrograde femoral approach is typically utilized from the contralateral limb. In patients in whom noninvasive imaging indicates a widely patent common femoral and proximal superficial femoral artery and body habitus is not prohibitive, an antegrade approach can serve as a useful alternative. In ambiguous lesions, pull-back pressure measurements, both before and after the administration of a systemic vasodilator such as papaverine or nitroglycerine or the application of a tourniquet to induce reactive hyperemia, can be useful in documenting the hemodynamic significance of a particular stenotic zone.³⁵ The utilization of gadolinium³⁶ or carbon dioxide³⁷ as contrast agents in patients with compromised renal function, although perhaps less effective in the periphery than in the aortoiliac vasculature, can minimize or eliminate the nephrotoxic effects associated with standard iodinated contrast medium.

Medical Treatment

Risk factor modification remains a cornerstone of the management of lower extremity occlusive disease. Smoking cessation has been shown to reduce the risk of disease progression, amputation, and cardiovascular mortality, and may lead to symptom relief in some patients. Smoking cessation has been best achieved with repeated physician assistance, group counseling, nicotine replacement or nicotinic receptor agonists, and antidepressant drug therapy in some patients. Weight and blood pressure reduction and aggressive efforts at lipid control should be addressed with every patient with atherosclerotic disease. Lipid-lowering therapy involves dietary modifications first and utilization of hydroxymethylglutaryl-coenzyme A reductase inhibitors to lower low-density lipoprotein (LDL) cholesterol and fibrates or niacin to raise high-density lipoprotein (HDL) cholesterol. Patients with lower extremity occlusive disease should have a

FIGURE 95.3. Magnetic resonance angiogram identifying short-segment occlusion of right superficial femoral artery, a lesion amenable to attempt at percutaneous therapy.

goal LDL cholesterol of less than 70 mg/dL.³⁸ Patients with diabetes should have aggressive control of blood glucose toward a goal hemoglobin A1C of less than 7%. Antiplatelet therapy in the form of either aspirin or clopidogrel is a critically important element of the treatment of established occlusive disease,³⁹ given its documented ability to prevent thrombosis and embolization and possibly even to arrest the progression of atherosclerosis. Aspirin and clopidogrel have both been shown to reduce cardiovascular morbidity and mortality in patients with PAD.^{40,41}

Strong evidence exists supporting the benefit of a supervised structured walking program⁴² in increasing the walking distance of patients with claudication. The benefit of walking outside of a structured regimen with close follow-up is more debatable.⁴³ Nevertheless, patients should be encouraged to “walk through” the onset of lower extremity pain, resting intermittently as required. Overall, pharmacotherapy has not had a significant impact on relieving symptoms of infrainguinal occlusive disease. There is some evidence to suggest cilostazol, a phosphodiesterase inhibitor, improves walking distance and quality of life.^{44,45}

While early studies showed that pentoxifylline, a rheologic agent, had beneficial effects on walking distance, later studies have questioned its clinical benefit.^{46–47} Similarly, although older studies suggested that prostanooids improved healing of ischemic ulcers, the current evidence does not support the utility of any systemic drug for the relief of ischemic rest pain or the treatment of ischemic ulcerations.^{48–50}

Indications for Revascularization

The two major indications for intervention of infrainguinal arterial occlusive disease are lifestyle-limiting claudication and limb-threatening critical ischemia. Less common indications for infrainguinal arterial reconstruction include trauma-related vessel disruption, popliteal artery entrapment syndrome, and femoropopliteal arterial aneurysm with thromboembolism. Infrainguinal revascularization for the treatment of peripheral vascular occlusive disease has been increasingly successful for

both long-term palliation of intermittent claudication and for the salvage of limbs threatened by critical ischemia.

Critical ischemia is associated with inevitable amputation for most patients unless revascularization is undertaken. Although there are certainly cases in which primary amputation represents the safest and most advisable solution in the face of irreversible ischemia, particularly for cases in which extensive infection or tissue necrosis is present, an attempt at revascularization is almost always indicated when a limb is threatened by severe ischemia. Improvements in endovascular technology and techniques as well as perioperative management and surgical technique have allowed progressively more distal revascularizations to be successfully completed in an older, sicker, and challenging patient population. In general, high rates of relief for claudication and up to an 80% to 90% limb salvage rate may be anticipated for patients with critical ischemia at institutions devoted to peripheral bypass surgery.^{51,52} Though the long-term durability of various endovascular revascularization approaches is not clear, similar rates of limb salvage in the short term to midterm have been demonstrated.

Claudication is a relative indication for intervention given the natural history of the disease, and it remains a subjective assessment on the part of both patient and surgeon as to the relative degree of disability a particular level of claudication pain represents. For example, two-block claudication in a younger patient whose livelihood depends on walking tolerance constitutes a more significant disability than the same degree of claudication in an older, retired individual able to attend to his or her daily affairs without significant consequence. Thus, proximal above-knee surgical reconstruction in a patient with disabling claudication and a patent popliteal artery with intact runoff may be justified in view of its minimal operative mortality, excellent long-term palliation, and absence of added risk of limb loss beyond that expected from the natural history of the disease process. Classically, it has been thought that the benign natural history of claudication does not warrant aggressive femorotibial reconstruction in patients with diffuse superficial femoropopliteal and tibioperoneal disease, though reconstruction will often provide symptomatic benefit and can be considered in a good-risk patient.

In recent years, the low morbidity of endovascular revascularization in combination with patient desire for intervention seems to have lowered the threshold for offering catheter-based revascularization for claudication. Patients once considered appropriate only for risk factor modification, exercise therapy, and medical treatment are now increasingly being offered percutaneous revascularization. Similarly, occlusive disease of the tibial vessels, once thought to be the exclusive domain of operative bypass, is increasingly being treated percutaneously.⁵³ Nevertheless, endoluminal revascularization is not without risk and is at present of limited durability. It is therefore prudent to follow the classical surgical axiom that because most patients with claudication remain stable for years, it is important to allow sufficient time for collaterals to develop; some patients may improve to such an extent that intervention proves unnecessary.¹¹

Approach to Revascularization

The last two decades have seen increasing utilization of endovascular revascularization of infrainguinal occlusive disease. In this light, it cannot be overemphasized that symptom status and not anatomic findings should serve as the basis for revascularization. Once the decision to intervene has been made, a variety of factors should be considered in choosing whether to proceed with an endovascular, surgical, or combined (hybrid) approach. The goals and outcomes of revascularization should be considered in the context of the individual patient's comorbidities, operative risk and overall life expectancy, the extent of the occlusive disease present, and the expected durability of the procedure.

Anatomic variables appear to be the key determinant of the success and durability of endovascular therapy. With the promulgation of endovascular therapy has arisen the need to classify the anatomic severity of disease in order to guide potential therapy and compare outcomes between various modes of revascularization. The Trans-Atlantic Intersociety Consensus Document on Management of Peripheral Arterial Disease (TASC) was published as the result of a multidisciplinary collaboration between key medical and surgical vascular societies in 2000 and an abbreviated update was published in 2007.^{13,54} This document classified infrainguinal occlusive lesions into classes A, B, C, and D based on the location of the lesion and the number, length, and severity of the stenoses and/or occlusions present. Their recommendations, which reflect current practice to a variable extent, include initial endovascular treatment for TASC A lesions, primary surgical treatment for TASC D lesions, and individualized tailoring of treatment for TASC B and C lesions depending on endovascular suitability and surgical risk. While a complete description of this classification schema and specific outcomes of endoluminal revascularization according to lesion severity are beyond the scope of this chapter, a few general principles are worth noting. The patency of endoluminal revascularization in general decreases the more distal the disease is and is less in patients with stenoses that are multiple, longer, and more severe.

Role of Endoluminal Therapy

A marked increase in the number and versatility of available balloons and stents has helped to fuel the increasing application of percutaneous technology. While a complete description of endoluminal treatment options and outcomes is beyond the scope of this chapter, a brief introduction is necessary. Percutaneous transluminal angioplasty is generally performed under local anesthesia with minimal intravenous sedation and as either a day surgical procedure or involving an overnight admission. Associated morbidity and mortality has significantly declined in recent years and overall complication rates are low. It is currently unclear whether technical failure changes the available surgical options. Contrast-induced acute renal failure remains the most common complication. With the development of hypo-osmolar and iso-osmolar contrast agents, the overall incidence has fallen to less than 6%,⁵⁵ although higher rates are found in patients with preexisting renal failure and diabetes.^{56,57}

Access site complications, predominantly pseudoaneurysms and arteriovenous malformations (AVMs), occur in 1% of patients.⁵⁸ Most of them can be managed conservatively, with close observation, serial hematocrit checks, and fluid and blood product replacement. Surgery is reserved for those patients with ongoing bleeding effecting hemodynamic instability or distal ischemia, or pseudoaneurysms or arteriovenous fistulas that fail to resolve on serial ultrasound imaging with several weeks of careful observation. Stable pseudoaneurysms in patients without coagulopathy can also be managed with ultrasound-guided compression therapy; more recently, ultrasound-guided thrombin injection into the sac has been used with good success.⁵⁹ Infection related to the placement of newer percutaneous closure devices utilized for puncture site control typically present several weeks to months after the percutaneous procedure. Rarely, maldeployment of these devices can lead to embolic or thrombotic sequelae causing compromise of distal flow.⁶⁰

Percutaneous transluminal angioplasty (PTA) for femoropopliteal lesions has generally yielded 1-year patency of approximately 77% and 65% for stenoses and occlusions, respectively. Three-year patency after PTA has been reported at 55% to 68% and 40% to 55% for stenoses and occlusions, respectively. Five-year patency data are more limited but have been generally reported to be about 55% and 42% after PTA for femoropopliteal stenoses and occlusions, respectively.¹³ Infrapopliteal PTA is generally even less durable, with primary

patency of approximately 50% at 1 year.⁵³ Review of the literature does not provide compelling evidence that stent placement improves the results of femoropopliteal PTA.⁶¹ Many practitioners thus utilize stents selectively for failure of PTA of superficial femoral artery lesions, though there is some evidence that primary stent placement yields higher short-term patency than PTA alone for femoropopliteal lesions.⁶²

There is a scarcity of high-level data comparing PTA and bypass surgery. There have been only four randomized trials, and these have included a heterogeneous group of patients, measured different outcomes, and generally included limited anatomic detail.^{63–66} Pooled analysis of these trials demonstrates that surgical bypass generally had superior patency to PTA at 1 year, but there were no differences in progression to amputation. Surgery was associated with increased postprocedure

7 complications in patients with CLI.⁶⁷ For patients with favorable anatomy and significant operative risk, and for the treatment of claudication in general, percutaneous therapy has

8 assumed a primary initial role. When medical therapy or percutaneous treatment has proven inadequate, open surgical revascularization remains the “gold standard” for those patients with disabling claudication. Furthermore, until the efficacy and durability of infrainguinal percutaneous intervention is better defined, surgical revascularization remains the “gold standard” for any patient with critical limb ischemia, especially those with extensive tissue loss. The relative roles of surgical and percutaneous intervention are actively being refined. It nevertheless appears that the rising popularity and success of femoral and tibial wire-based interventions may be reducing the volume, or ultimately just delay the timing, of subsequent infrainguinal reconstructive surgery. Furthermore, many patients are best treated with a combination of percutaneous and open surgical therapy, often in a single procedure (hybrid procedure). In many instances, endoluminal and open surgical revascularization are thus complementary modes of therapy.

Operative Management

Successful infrainguinal bypass grafting requires adequate arterial inflow. While aortobifemoral, femorofemoral, and axilofemoral bypass grafting remain routinely performed inflow procedures, aortoiliac angioplasty and stenting are increasingly becoming the preliminary procedures performed to attain sufficient inflow prior to construction of a more distal bypass graft. At times, the necessity of improving the inflow to support an infrainguinal graft is determined intraoperatively, either by direct visual assessment of the arterial flow at the desired donor site or by comparison of a transduced pressure tracing from the donor site with that of a systemic pressure tracing, typically obtained from a radial arterial line. Of equal importance to the outcome of any infrainguinal graft is target vessel selection. In general, the target vessel should be the least diseased artery that is the dominant supply to the foot. If tissue necrosis is present, restoration of pulsatile flow to the foot is often required to obtain full and sustained wound healing.

Infrainguinal surgical bypass can be performed under general anesthesia or, in the appropriate patient, regional spinal or epidural anesthesia. In cases involving multiple sites of dissection, such as those necessitating more tedious arm vein or lesser saphenous vein harvesting, the procedures are particularly amenable to a two-team approach, with the time saved having direct benefit in minimizing the total anesthetic load and physiologic insult. The patient is sterilely prepped and draped from the midabdomen down to the foot. It is our practice to work from proximal to distal, first exploring the inflow artery and exposing the venous conduit. We then explore the site proposed for the distal anastomosis, as high-quality preoperative imaging has already defined a suitable target vessel.

For patients with superficial femoral artery disease, the initial dissection is most commonly at the level of the common femoral artery. This vessel is exposed through a longitudinal or

FIGURE 95.4. In the setting of orificial profunda femoral artery disease, extending the common femoral arteriotomy into the origin of the profunda and performing a profundaplasty will maximize profunda flow in the event of graft thrombosis.

oblique incision centered directly over the femoral pulse. Lymphatic tissue overlying the femoral vessels is best ligated and divided to prevent the postoperative development of lymph fistulas or lymphoceles. The severity of any concomitant common femoral and profunda femoral disease and the level of reconstruction planned dictate the extent of exposure of the femoral vessels. In most instances, the dissection extends from the inguinal ligament to the common femoral artery bifurcation, where the origins of the superficial and profunda femoral arteries are individually isolated.

If a profundaplasty is required, the dissection is extended distally along a sufficient length of the profunda femoral artery to attain an endpoint suitable for clamping and sewing (Fig. 95.4). Similarly, the inguinal ligament can be partially divided to facilitate access to the distal external iliac artery in cases in which a more extensive proximal endarterectomy is necessary. In these circumstances, it is customary to close the endarterectomized bed with a vein, bovine pericardial, or Dacron patch, onto which the proximal anastomosis can subsequently be attached.⁶⁸ In patients with a hostile groin crease from prior surgery or radiation therapy or in obese, diabetic patients with an intertriginous rash at the inguinal crease, meticulous skin preparation, close attention to draping, careful surgical technique, and judicious use of a short course of intravenous antibiotic therapy help minimize the chances of a postoperative wound or graft infection.

If all or part of the superficial femoral artery is spared of significant atherosclerotic involvement, the proximal anastomosis can be moved distally as dictated by the particular anatomic pattern of disease, and a so-called “distal origin graft” can be fashioned⁶⁹ (Fig. 95.5). This situation is particularly applicable to the diabetic population, in whom infrapopliteal disease is the rule and sparing of the superficial femoral and popliteal arteries is not uncommon. It is also utilized in situations in which conduit is sparse and a moderately diseased proximal vessel is accepted as an inflow source for a more distal origin bypass graft in the interests of performing a fully autologous vein graft rather than utilizing prosthetic material. An increasingly popular approach when only limited conduit is available is to combine, either concurrently in the operating room or as a staged preoperative procedure, catheter-based treatment of the superficial femoral or popliteal artery inflow with more distal bypass.⁷⁰

The above-knee popliteal vessel is easily exposed through a medial thigh incision, with subsequent posterolateral retraction of the Sartorius muscle. The popliteal artery with its accompanying vein and nerve is found just posterior to the femur. The

FIGURE 95.5. Arteriogram indicating preservation of the superficial femoral artery and popliteal arteries with midcalf occlusions of all three infrageniculate vessels. This anatomic pattern of disease is amenable to “distal origin” vein grafting from the below-knee popliteal or proximal posterior tibial artery to the dorsalis pedis artery.

vessel is palpated to determine the presence of atherosclerotic plaque, which will guide the extent of dissection and the optimal bypass target site. The below-knee popliteal artery is also exposed through a medial incision in the proximal calf (Fig. 95.6). If the saphenous vein is to be harvested, the incision is made directly over the vein to minimize the creation of devascularized skin flaps. With the exposed vein carefully protected, the incision is carried through the deep muscular fascia and the medial head of the gastrocnemius is reflected posterolaterally to expose the below-knee popliteal fossa. The distal popliteal artery is then dissected free from the adjacent tibial nerve posteriorly and popliteal vein medially. If the distal target is the tibioperoneal trunk, the dissection is continued along the anteromedial surface of the distal popliteal artery after dividing the origin of the soleus muscle from the tibia (Fig. 95.7). In instances in which the below-knee popliteal artery has previously been exposed or

where sepsis is involved, a lateral approach with excision of a segment of proximal fibula is a useful alternative approach to the below-knee popliteal artery.

Although exposure of the proximal posterior tibial and peroneal vessels can be gained by extending the tibioperoneal trunk dissection distally, more distal exposure of these vessels is best gained through targeted medial incisions. The posterior tibial artery is found beneath the divided musculotendinous origin of the soleus muscle, and the peroneal artery is deeper and more lateral. The posterior tibial artery at the level of the ankle is a relatively easier target given the proximity of the vessel to the skin surface. The initial incision is made just posterior to the medial malleolus, and the artery exposed by division of the overlying retinaculum. Further distal dissection allows access to the bifurcation and medial and lateral plantar branches.⁷¹ The more distal peroneal artery may be approached

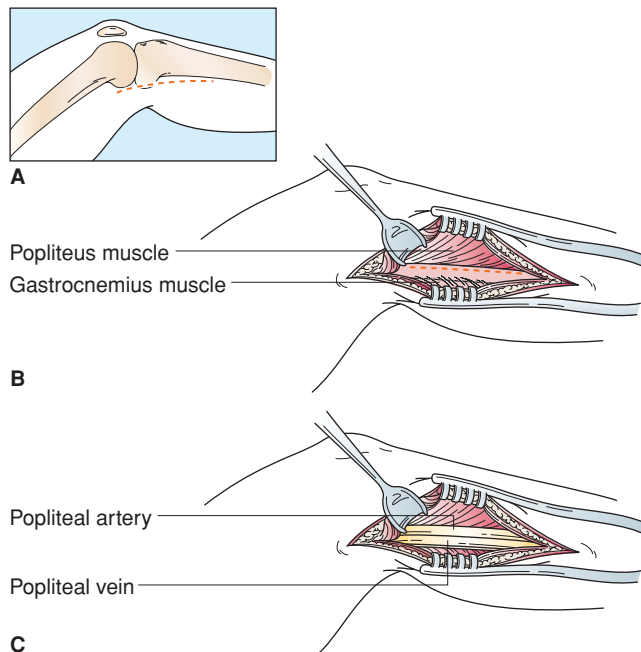

FIGURE 95.6. Exposure of the popliteal artery below the knee. The medial incision is made directly overlying the course of the greater saphenous vein.

laterally via an incision placed over the distal fibula. Excision of a short segment of fibula will expose the underlying artery.

The anterior tibial artery is typically approached from the anterolateral aspect of the calf (Fig. 95.7) and is found deep within the anterior compartment with the adjacent deep peroneal nerve and anterior tibial veins. It is best identified by developing the intermuscular plane between the tibialis anterior muscle belly medially and the extensor digitorum longus

FIGURE 95.7. Placement of incisions for femoropopliteal and femorotibial bypass and for greater saphenous vein harvest. These should avoid the incision lines for a below-knee amputation.

laterally. The dorsalis pedis artery is easily exposed through an axial incision on the dorsum of the foot just lateral to the extensor hallucis longus tendon (Fig. 95.7). The artery lies just deep to the extensor retinaculum.

Autogenous Vein Bypass

- 9 In general, infrainguinal bypass surgery is best performed with autogenous vein conduit, preferably the ipsilateral greater saphenous vein if available.⁷² This preference is particularly true for grafts extending below the knee, where prosthetic conduits of Dacron or polytetrafluoroethylene have significantly poorer patency rates. The first report of a femoropopliteal bypass graft using autogenous greater saphenous vein in a reversed orientation was by Kunlin in 1951.⁴ Given the orientation of the vein valves, the vein can be reversed such that the distal end of the vein is sewn to the proximal inflow artery and the larger proximal end of the vein is sewn to the distal outflow artery. However, it is our general practice to utilize the greater saphenous vein in the nonreversed orientation, as will be discussed shortly. The vein is harvested through a long incision overlying the course of the vein or by more tedious but less invasive sequential skip incisions with intervening cutaneous skin bridges (Fig. 95.7). All side branches are ligated and after harvest, the vein is cannulated and gently dilated with a solution containing heparin and papaverine to assess its suitability. Veins with chronic fibrosis or that fail to dilate to a diameter of 3 mm or greater will likely have poor long-term function.

An alternative and less invasive approach to saphenous vein harvest involves the use of endoscopic technology. In the case of harvesting of the greater saphenous vein, small skin incisions are made over the saphenofemoral junction and the distal vein, and guided by a videoscope inserted distally and advanced proximally, the side branches of the vein are serially identified and either cauterized or clip-ligated. The vein is then divided distally and proximally and removed, leaving the overlying skin undisturbed. Advocates of this method cite a significant reduction in wound complication rates and reduced rates of hospital stay.⁷³ Although it has not been widely adopted by vascular surgeons, the technique does have particular theoretical appeal in cases, for example, when contralateral saphenous vein is to be utilized or the healing potential of the donor leg is compromised.

For prosthetic grafts, a tunnel is usually fashioned through the subsartorial plane between the groin incision and the above-knee popliteal space in the interests of protecting the graft from subsequent infection. For vein conduits, it remains the surgeon's preference as to whether the graft is tunneled deeply or in a superficial location in the subcutaneous space. The more superficial configuration greatly facilitates ongoing clinical examination and ultrasonographic surveillance as well as later surgical revision, but carries a risk of graft exposure should there be wound healing problems. Occlusion from trauma to grafts placed superficially has been of theoretic, but not practical, concern.

It is our practice to perform the proximal anastomosis prior to the distal anastomosis. First, this allows confirmation of adequate inflow before the bypass is performed. Second, performance of the proximal anastomosis first allows the graft to be tunneled and tailored to appropriate length under arterial pressure. This is of critical importance to prevent kinking along the length of the graft. Some surgeons also prefer to mark the distended graft to ensure against mechanical twisting of the graft during the tunneling process. An additional benefit of performing the proximal anastomosis first is that adequacy of flow through the graft can be assessed, both before and after tunneling, with brief release of the clamp.

Prior to occluding the target vessel, the patient is systemically anticoagulated with 5,000 to 10,000 units of heparin. Additional heparin is given throughout the procedure to maintain the activated clotting time near the target range of 250 to 300 seconds.

After allowing sufficient time for the heparin to circulate, atraumatic vascular clamps are placed proximally and distally and the artery is incised. The vein is then spatulated and a beveled anastomosis carried out. Typically, a 5-0 monofilament suture of polypropylene is used for the femoral anastomosis, a 6-0 used at the popliteal level, and a very fine 7-0 suture used at the tibial or pedal level. If the target tibial vessel is deep within the calf and visibility is challenging, a technique of “parachuting” the heel of the distal anastomosis is often employed. After completing the proximal anastomosis, the graft is carefully tunneled under arterial pressure. Occasionally, such extensive calcification of the target vessel is encountered that the risk of a significant injury from clamping, even with the minimally traumatic clamps in use today, is prohibitively high. In such cases, proximal inflow and distal artery backbleeding can be controlled by occlusion balloons placed intraluminally. For distal anastomoses at the knee

or more distal level, another alternative technique is the use of a proximally placed sterile pneumatic tourniquet. This technique is particularly advantageous when sewing to diminutive distal tibial or pedal targets, where the impact of a crush injury or plaque dislodgment on graft function could be considerable. Removing the need for clamps by using the tourniquet has two further advantages. First, it improves the operative visibility. Second, and more importantly, given that less longitudinal and circumferential dissection is needed, the degree of vessel spasm and venous bleeding that frequently accompanies vessel exposure at this level is kept to a minimum.

Flow through the graft and the outflow arteries is assessed following completion of the bypass with a continuous wave Doppler. Ideally, a contrast angiogram is also performed after directly cannulating the proximal graft (Fig. 95.8); this allows for immediate repair of any technical defects that are identified,

FIGURE 95.8. Intraoperative completion arteriograms of distal anastomoses to the above-knee popliteal (A), below-knee popliteal (B), distal posterior tibial (C), and dorsalis pedis (D) arteries.

such as intraluminal thrombus, twisting or kinking of the graft, or retained valve cusps.⁷⁴ Intraoperative completion duplex ultrasonography is an additional sensitive screen for hemodynamically significant abnormalities within the graft,^{75,76} and its use further serves to prevent early graft loss caused by correctable technical problems.

Current reports of the 5-year results of reversed saphenous vein graft using modern techniques have been excellent, with primary and secondary patency rates of up to 75% and 80%, respectively, and limb salvage rates as high as 90%^{77–79} (Table 95.1).

In Situ Grafting. There has been ongoing enthusiasm in some circles for in situ vein bypass grafting, whereby except for its proximal and distal extent, the greater saphenous vein is left undisturbed in its native bed. This technique was first described in 1962,⁸⁰ but was later popularized by Leather et al. in the late 1970s.⁸¹ Recent reports of in situ saphenous vein grafting have indicated 5-year graft patency rates of up to 80% and limb salvage rates of 84% to 95%^{51,52,78,82–84} (Table 95.1).

The in situ approach minimizes trauma to the vein during excision and handling and in theory enhances preservation of the vasa vasorum and endothelium. It further lowers the considerable risk of wound healing complications seen with traditional vein harvesting, increases vein utilization, and facilitates the creation of more technically precise anastomoses because the proximal and distal vein diameters are more closely matched to those of the inflow and outflow target vessels (Fig. 95.9). The extent of the proximal vein mobilization is dictated by the location of the saphenofemoral junction relative to the proposed site of the proximal anastomosis. It may at times be necessary to perform an endarterectomy of the superficial femoral artery if the length of proximal vein is insufficient. Lysis of the valve cusps is obligatory given the nonreversed configuration and is facilitated by newer, less traumatic valvulotomes that function safely through the blinded segments of undissected graft. Critics of this technique argue that the advantages listed previously have not translated into improved graft function or patency. They further argue that the time required and dissection involved in finding and ligating substantial side branches that can develop into physiologically important arteriovenous fistulas that “steal” distal flow obviates the stated benefits of this approach. Newer techniques using angiography and endoluminal coiling⁸⁵ of larger side branches may help to minimize these concerns.

Angioscopic assisted valve lysis has been employed for over a decade, but has not gained widespread favor. Although there is a significant learning curve with this technology and operative times, at least initially, are significantly prolonged, advocates cite fewer wound complications, shorter hospital stays, and decreased recuperative periods as potential benefits. Proponents

of routine angiography for direct visualization of valve lysis stress its particular utility in demonstrating such unsuspected endoluminal venous pathology as phlebotic strictures, webs, and fibrotic valve cusps.⁸⁶ This adjunct may be particularly useful in cases in which arm vein is used because endoluminal pathology is more frequently encountered and is presumably responsible in part for suboptimal results.⁸⁷

Nonreversed Saphenous Vein Grafts. Recognizing the many practical advantages inherent to the in situ technique, some surgeons have modified the approach to infrainguinal bypass grafting with venous conduit to incorporate several of the same principles.⁵¹ In particular, if the harvested vein is tapered to any significant extent, it is used in a nonreversed fashion. By optimizing the size matching between the artery and vein at both the proximal and distal anastomosis sites as discussed previously, one can often accept for use smaller veins than would be suitable for reversed vein grafting. The nonreversed configuration also allows preservation of the saphenous vein hood, which both extends the available conduit length and is especially beneficial when the femoral artery is thick walled and diseased.

The vein is harvested and dilated in a similar fashion to reversed vein grafts and the cusps of the proximal valve of the greater saphenous vein are excised under direct vision with fine Potts scissors. There are currently two main types of valvulotomes available. The modified Mills valvulotome is a short, metal, hockey stick-shaped cutter that can be introduced through the distal end of the vein or through the side branches. After the proximal anastomosis is performed, and with the perused conduit on gentle stretch, the valves are carefully lysed in a sequential fashion by pulling the valvulotome inferiorly. An alternative, recently designed self-centering valvulotome allows lysis of all valves in a single pass and is thought by some to be less traumatic. Once acceptable pulsatile flow is ensured, the distal anastomosis is performed in the standard fashion.

It is important to note that similar patency rates have consistently been demonstrated regardless of which technique is applied,^{83,84} and so surgeon preference and comfort level is an acceptable reason for choosing one method over another.

Prosthetic Bypass. It is recommended that infrainguinal bypass surgery be performed with saphenous vein or an autologous substitute whenever feasible given the clearly demonstrated enhanced patency rates.^{51,88} Some institutions more frequently rely on prosthetic grafts. When the distal target is the above-knee popliteal artery and the tibial outflow is relatively well preserved, this is an acceptable approach, as patency rates in this situation approach those of vein grafts.⁸⁹ A variety of surgical adjunctive procedures, from patching the distal anastomotic target vessel to the creation of a distal arteriovenous fistula or

FIGURE 95.9. A: In the in situ method of infrainguinal reconstruction, the saphenous vein is left undisturbed in its native bed except for at the proximal and distal anastomotic sites, in this case the common femoral artery and the tibioperoneal trunk, respectively. B: The saphenofemoral junction is transected in the groin, the venotomy in the femoral vein is oversewn, and the proximal end of the saphenous vein spatulated in preparation for anastomosis. C: After the first venous valve is excised under direct vision, the graft is anastomosed end to side to the femoral artery. Flow is then restored through the vein graft and the valvulotome passed from the distal end to lyse the residual valves (D) before the distal anastomosis is performed (E).

various autogenous vein cuffs interposed between the distal prosthetic and the target artery, have all been attempted as a means of improving the patency rates of grafts extending below the knee.⁹⁰ More recently, flared grafts designed to minimize turbulence and shear stress between the prosthetic and native vessel have gained some popularity. Polyester (Dacron) and polytetrafluoroethylene (Teflon) grafts are the two main types of prosthetic available and, as in other anatomic positions, available data show generally equal results with either choice. The entire procedure is carried out through two small proximal and distal incisions between which the graft is tunneled anatomically. The selection of a 6- or 8-mm graft is dictated by the size of the native vessels.

Reoperative Bypass Surgery. As the patient population treated by vascular surgeons has increased in age, and more and more challenging cases are accepted for primary treatment, there has been a corresponding increase in the incidence of reoperative bypass surgery performed for infrainguinal arterial occlusive disease. Such reoperative procedures are particularly challenging, both because of the scarring present at the inflow and outflow target sites and because there is typically a lack of ipsilateral greater saphenous vein. Whenever possible, the first

problem is addressed by choosing anastomotic sites just above or below the previous touchdown points, thereby avoiding dissection through often densely scarred tissue planes. When ipsilateral greater saphenous vein is absent because of prior infrainguinal or coronary artery bypass surgery or prior saphenous vein stripping, there are a number of alternative conduit sites available. Investigators examining the consequence of using the contralateral greater saphenous vein in these situations found it to be the optimal conduit; despite the presumably high incidence of contralateral lower extremity as well as coronary occlusive disease in this population, the short- and long-term impact was found to be minimal.⁹¹

In the absence of any greater saphenous vein, preoperative venous duplex ultrasonography is employed to evaluate the cephalic and basilic veins of the arms and the lesser saphenous veins of the legs in an effort to determine the best conduit available. Often the veins distal to the antecubital crease are scarred and of small caliber, but their more proximal counterparts are often of excellent size and quality. The use of arm veins in general can be extremely technically challenging and for that reason has not been universally adopted. The dissection of the basilic vein can be particularly tedious as it has multiple side branches and

FIGURE 95.10. Creation of a composite graft from two or more segments of arm vein or lesser saphenous vein is sometimes necessary to obtain the desired length of fully autogenous conduit for infrainguinal bypass. A widely spatulated venovenostomy is optimal.

lies adjacent to several important nerves. As arm veins are often relatively short, a venovenostomy is often required to create composite grafts long enough to complete the arterial reconstruction (Fig. 95.10). This is performed with generous spatulation of each vein hood to create a widely patent vein-to-vein anastomosis. Given their thin-walled nature, arm vein grafts are also quite prone to twisting and kinking, and special care must be taken during the tunneling process to avoid these problems. The more proximal arm veins can be relatively large, and it is often advantageous to use one or more of the segments in a nonreversed fashion to better match the graft to the inflow vessel size.

Not surprisingly, the results of reoperative infrainguinal bypass surgery do not match those of primary reconstruction. With autogenous vein, 5-year patency rates of 60% and limb salvage rates of 70% to 80% have been reported.^{26,91} Coumadin is often used postoperatively in patients with compromised outflow or in whom the conduit was of marginal quality and has been associated with improved long-term patency.⁹²

Postreconstruction Management

- 10** Many patients undergoing surgical reconstruction for arterial insufficiency require one or more adjunctive operative procedures of their foot. Small, uninfected ulcerations of the toe or foot often can be safely managed conservatively. However,

larger, gangrenous lesions of the toe, forefoot, or heel usually require débridement of all necrotic tissue at the completion of the revascularization procedure. If the ischemia is particularly severe or infection is present, a toe or transmetatarsal amputation may be necessary in order to achieve a margin of healthy tissue. This is particularly important in patients with diabetes or end-stage renal disease, in whom persistent infection or necrosis can result in limb loss despite the presence of a well-revascularized extremity. The wounds are usually left open and treated with saline wet-to-dry dressings or newer, vacuum sponge dressings. Serial débridements on the ward or in the operating room are often necessary for the larger wounds, which can then be surgically closed after an interval healing period or allowed to slowly close via secondary intention over time.

Unless otherwise contraindicated, all patients are maintained indefinitely on an antiplatelet regimen with either aspirin or clopidogrel following surgical bypass. As stated previously, in cases in which a graft is at increased risk of failure, such as in the setting of reoperation or in cases in which compromised outflow or a marginal conduit was accepted, the antiplatelet agent may be supplemented with heparin and then warfarin.⁹² Patients with distal calf or pedal incisions should be placed on bed rest with leg elevation in the early postoperative period to minimize leg swelling and wound healing complications. Thereafter, aggressive rehabilitation maximizes the chances of and shortens the time to a return to full function after extensive reconstructive surgery. Ongoing risk factor modification in the form of smoking cessation, lipid reduction, exercise, blood pressure management, and diabetic blood sugar control is of further paramount importance in minimizing the risk of disease progression or recurrence.⁹³

Graft Failure and Surveillance

Postoperative graft failures are typically classified according to the time interval from surgery as early, intermediate, or late. Graft thrombosis occurring within 30 days, so-called “early graft failures,” are generally thought to be a result of technical or judgment errors by the surgeon. Included in this list would be such technical errors as twists, kinks, incompletely lysed valves, or anastomotic defects, as well as judgment errors in using a poor-quality vein or targeting an outflow vessel with inadequate runoff to support the graft. Intermediate graft failures include those between 30 days and 2 years and are generally attributed to the proliferation of intimal hyperplasia at the anastomoses or prior valve sites within the graft (Fig. 95.11). Late graft failures occurring beyond 2 years are typically a result of the progression of atherosclerotic occlusive disease within the inflow or outflow arteries.

Given the known incidence of graft failure and the potentially dire consequence in terms of limb salvage or preservation of limb function in a patient with limited options for secondary or tertiary bypass, the ability to maintain graft patency through early identification and prompt correction of graft stenoses is of paramount importance.⁹⁴ Serial postoperative surveillance scanning with a duplex ultrasound has proven an excellent means of accurately identifying hemodynamically significant stenoses within the vein graft that threaten the graft patency.⁹⁵ Velocity criteria have been developed for high-grade lesions that may warrant either more intensive surveillance or prophylactic intervention. Absolute velocities less than 40 cm/s or greater than 300 cm/s or a threefold increase in velocity in one segment compared with that of an adjacent segment are all indicative of impending graft failure. Confirmation by angiography and expeditious treatment by percutaneous cutting balloon angioplasty, surgical patch angioplasty, or interposition grafting of such significant lesions minimizes the risk of graft thrombosis and ensures optimal long-term graft patency.

FIGURE 95.11. Arteriogram demonstrating severe stenosis of distal graft from intimal hyperplasia, likely at the prior valve site.

Complications

The most commonly seen major complications of infrainguinal bypass surgery are cardiac in nature and include myocardial infarction, congestive heart failure, and arrhythmias. In a recent review spanning 20 years and involving more than 1,600 procedures, the perioperative myocardial infarction rate was 3%, and the rate of cerebrovascular accident was 1%.⁷⁹ Patients with diabetes mellitus or preoperative renal insufficiency are at particular risk for developing postoperative renal failure (defined as an elevation of serum creatinine >3 mg/dL, doubling of the serum creatinine, or the need for hemodialysis), which is seen in up to 2% of patients overall. Patients undergoing lower extremity revascularization are also prone to wound complications, given the length of incisions and the prolonged operating times often required. Wound infection, including cellulitis, abscess formation, wound dehiscence, and skin flap necrosis, are most commonly seen and can best be avoided by gentle handling of the tissue, the use of skin bridges, and careful avoidance of skin flaps during vein harvesting. Postoperative hematomas, usually caused by slow capillary or venous oozing, or seromas are seen in 5% of patients, and less commonly encountered hemorrhage, typically a result of either a slipped vein branch ligature or anastomotic disruption, is seen in less than 1% of cases.

CHAPTER 96 ■ LOWER EXTREMITY AMPUTATION

MATTHEW J. SIDEMAN, KEVIN E. TAUBMAN, AND BRADLEY D. BEASLEY

KEY POINTS

- 1 More than 105,000 lower extremity amputations are performed in the United States annually.
- 2 The vast majority of lower extremity amputations are performed for complications of diabetes or arterial insufficiency.
- 3 Emergent amputation is indicated in the face of uncontrolled or ascending infection.
- 4 Primary amputation is occasionally indicated in cases of treatment for lower extremity trauma.
- 5 Revascularization is often performed in conjunction with a minor amputation, either simultaneously or as a staged procedure.
- 6 The choice of amputation level depends on the indication for the procedure, the condition of the patient, and the rehabilitation potential of the patient.
- 7 The energy required to ambulate following a lower extremity amputation increases with ascending level of amputation.

Surgeons are often involved in treating patients requiring lower extremity amputation. An increasing incidence of diabetes, peripheral arterial disease, and the aging population has put more patients at risk for amputation. Advances in the treatment of vascular disease, both surgical and endovascular, have worked to counteract these trends and keep the number of amputations performed relatively stable. Feinglass et al. demonstrated a decrease in major amputation rates in the 1980s after widespread adoption of distal bypass surgery.¹ It is believed that the substantial increase in percutaneous interventions may further contribute to improved limb salvage rates.

- 1 Despite these advances, recent estimates show that more than 105,000 lower extremity amputations are performed in the United States annually.² Clinical judgment is critical to a successful outcome. Factors to consider are primary versus staged amputation, initial versus redo revascularization, and timing and level of amputation. The surgeon must remember that the goal is to maintain maximal function of the patient, not necessarily maximal length of the limb. Consequently, experience of the surgeon has been shown to be key to a successful outcome.³

INDICATIONS

- 2 Most lower extremity amputations are performed for complications of diabetes or arterial insufficiency (Table 96.1). Chronic infection and trauma account for less than 10% of the total number of amputations. Other indications include neuroma, frostbite, malignancy, chronic pain, arterial embolization, venous insufficiency, and cryoglobulinemia.⁴

Elective lower extremity amputation in diabetic and vascular patients is indicated for gangrene (dry gangrene), gangrene with infection (wet gangrene), unremitting and nonreconstructable rest pain, and nonhealing ulcers. The goal of the operation is to remove all nonviable tissue, relieve ischemic rest pain, ensure primary wound healing, and facilitate rehabilitation. Elective amputation should only be performed following an evaluation for revascularization procedure by a surgeon capable of performing such procedures. Veith et al.⁵ reported that 96% of patients who underwent lower extremity arteriography for limb-threatening infrainguinal arteriosclerosis were candidates for arterial reconstruction. Advances in percutaneous management have expanded treatment options to patients who were not otherwise operative candidates. Not

all patients are candidates for arteriography, including those with chronic renal insufficiency, organic brain syndrome, nonfunctional limbs, fixed joint contractures, insensate feet, and extensive gangrene.

Spinal cord stimulation (SCS) may offer a chance for limb salvage for patients with chronic ischemia in whom reconstruction is not an option. Based on Melzack and Wall's theory for treatment of chronic pain,⁶ the mechanism of pain relief and increased blood flow in end-stage peripheral vascular disease is unclear. Despite this, there is peripheral vasodilatation on the microvascular level, which leads to pain relief,⁷ increased claudication distance,⁸ ulcer healing,⁹ and possible limb salvage.^{7,10,11} The 1-year foot salvage rate is 60% to 70% on average, according to a review of the literature.¹² SCS is only appropriate when surgery for revascularization is no longer possible. Furthermore, SCS only dilates microvasculature and does nothing for the underlying, progressive peripheral vascular disease that is causing the ischemia. SCS, therefore, is only a temporizing measure, but can potentially give an extended functional period with a procedure that is well tolerated and relatively simple to perform.¹² Recently, Gersbach et al. have shown that the benefits of SCS persist longer than initially thought.¹³

- 3 Emergent amputation is indicated in the face of uncontrolled or ascending infection. In the case of uncontrolled sepsis, it may be a lifesaving maneuver. Similarly, a diabetic patient with a foot abscess constitutes a surgical emergency. Frequently, incision and drainage with or without a toe or a combined toe and metatarsal resection is sufficient to control the acute problem. The wounds should be left open in the setting of acute infection. If the process extends beyond the foot, a staged amputation should be performed proximal enough to control the infection. This can include an ankle disarticulation, a guillotine below-knee amputation (BKA), a knee disarticulation, or a guillotine above-knee amputation (AKA). Disarticulations have the advantage of preserving limb length and avoiding an open bone in the incision. After the infection is controlled, the appropriate amputation can be completed. A one-stage primary above-knee amputation can be considered in patients who are nonambulatory, have infection involving the entire lower leg, have a fixed knee contracture, or have a nonfunctional limb. Patients who are too unstable for surgery can be temporized with a cryoamputation.¹⁴
- 4 Primary amputation is occasionally indicated as treatment for severe lower extremity trauma. Both penetrating and blunt

TABLE 96.1 INDICATIONS/CONTRAINDICATIONS**INDICATIONS FOR LOWER EXTREMITY AMPUTATION**

■ INDICATION	■ PERCENTAGE
Complications of diabetes mellitus	60–80
Nondiabetic infection with ischemia	15–25
Ischemia without infection	5–10
Chronic osteomyelitis	3–5
Trauma	2–5
Miscellaneous (neuroma, frostbite, tumor, pain, nonhealing wound)	5–10

injuries of the lower extremities are frequently associated with vascular, nerve, bone, and extensive soft tissue injuries. Several treatment guidelines have been developed for lower extremity trauma. Lange¹⁵ recommended primary amputation for open tibial fractures with associated vascular injuries if the posterior tibial nerve was disrupted in an adult or if the duration of warm ischemia was greater than 6 hours in a crush injury. In addition, he suggested that primary amputation was relatively indicated in patients with polytrauma, severe ipsilateral foot injuries, and an expected protracted postoperative course. These suggestions are supported in work by Bosse et al.¹⁶ demonstrating that, in the case of high-energy lower extremity trauma, amputation and reconstruction have equal functional outcomes at 2 years. Additional guidelines have been provided by Johansen et al.,¹⁷ who devised a Mangled Extremity Severity Score (MESS) to predict the need for amputation based on the extent of skeletal or soft tissue damage, limb ischemia, shock, and age. Unfortunately, none of these guidelines are predictive of functional recovery in patients who undergo limb salvage.¹⁸ Therefore, treatment with primary amputation is an extremely difficult decision and requires extensive clinical judgment, as well as multidisciplinary input. Contributing factors include the severity of the injury, the overall clinical status, and the ultimate rehabilitation potential of the patient.

EVALUATION FOR REVASCULARIZATION

Modern vascular surgery techniques allow successful limb salvage in situations not previously possible. All patients who present for possible lower extremity amputation, including minor amputations, should have their peripheral vascular circulation evaluated preoperatively. Any patient with absent pedal pulses or abnormal ankle-brachial indices should be evaluated by a vascular surgeon skilled in both open and endovascular revascularization techniques. The evaluation may require only a thorough history and physical examination if there is an obvious contraindication to revascularization (e.g., nonfunctional limb, severe organic brain syndrome). Noninvasive vascular laboratory examinations are a mandatory minimum for patients with abnormal vascular examinations. Additional imaging with either multidetector, helical computed tomography angiography (CTA), magnetic resonance angiography (MRA), or contrast angiography can be done based on the patient's initial evaluation and vascular laboratory results. The information obtained from these tests is heavily dependent on the quality of the machinery, the skill of the technologist, and the knowledge of the interpreting physician. All of these factors

must be taken into account when deciding which test to order. Contrast arteriography should not be considered a *diagnostic* examination. It may, however, be necessary to fully define the patient's anatomy and determine suitability for reconstruction. It is preferred to perform this invasive procedure for preoperative planning or for planned percutaneous intervention.

Exponential advances in endovascular techniques have occurred over the past 10 years. These have found their way into the peripheral circulation and have applicability in limb salvage. Percutaneous techniques include conventional balloon angioplasty, stenting (including balloon-expandable, self-expanding nitinol, and covered stents), CryoPlasty, and percutaneous atherectomy (including laser, directional, and rotational). The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial showed no significant difference in amputation-free survival among patients with critical limb ischemia when randomized to open or percutaneous revascularization.¹⁹

In terms of surgical reconstruction, upper extremity²⁰ and cryopreserved cadaver vein²¹ have increased the options for conduit in limb salvage situations. Prosthetic grafts with vein cuffs^{22,23} provide other alternatives when appropriate autogenous conduit is not available. More recently, a heparin-bonded prosthetic graft has been introduced and early studies show promising results.²⁴ An operation for limb salvage should never be denied *only* for lack of conduit.

- 5 Revascularization is often performed in conjunction with a minor amputation, either simultaneously or as a staged procedure. This allows management of the acute problem of sepsis and the underlying chronic ischemia. Caution must be taken if there is active infection and the only available conduit is prosthetic for fear of infecting the graft. Amputation with control of infection followed by revascularization is the more prudent course. In extreme cases, a limited amputation can be combined with revascularization and a tissue transfer (free or rotational flap) to achieve limb salvage.^{25,26}

SELECTION OF AMPUTATION LEVEL

General

- 6 The choice of amputation level depends on the indication for the procedure, the condition of the patient, and the rehabilitation potential of the patient. The most common amputation levels are illustrated in Figure 96.1. Because most amputations are performed for complications of diabetes or arterial insufficiency, the selected level must remove all nonviable, painful tissue; allow primary healing; and maximize rehabilitation potential. Selection of the amputation level for malignant disease is dependent on the biologic characteristics of the neoplasm and is beyond the scope of this chapter.

The general medical condition and the rehabilitation potential of the patient are important factors in deciding to proceed with amputation and in selecting the appropriate level. If a patient is ambulatory and independent preoperatively, the level with the greatest likelihood of maintaining function should be selected. If the patient is not ambulatory or has significant comorbid conditions, the primary wound-healing rate should be the determining factor.

Specific Situations

Aggressive attempts to salvage a distal amputation level are not indicated for patients who are unlikely to ambulate with a prosthesis.²⁷ For example, patients with fixed joint contractures greater than 15 degrees at the knee or 10 degrees at the hip are unlikely to ambulate with a prosthesis. Below-knee amputations are relatively contraindicated in patients with

FIGURE 96.1. Common amputation levels for the lower extremity.

paraplegia because flexion contractures at the knee can lead to stump ulceration.

Energy Requirement

- 7** The energy required to ambulate following a lower extremity amputation increases with ascending level of amputation. The more proximal the amputation, the less likely a patient will be able to ambulate postoperatively. Table 96.2 illustrates the increased energy cost of the common lower extremity amputations. In clinical practice, the most significant increase is between below- and above-knee amputations. Ambulation on an above-knee prosthesis requires the use of muscle groups poorly suited for that purpose. These increased energy costs are minor issues for young trauma or cancer patients; however, they may represent a considerable obstacle for the older diabetic or vascular patient.

TABLE 96.2

RESULTS

REHABILITATION ENERGY COST OF AMPUTATION AT VARIOUS LEVELS

■ AMPUTATION LEVEL	■ ENERGY COST
Digital or ray	Minimal (except first ray)
Transmetatarsal	Minimal during normal walking
Below knee	30%–60% increase in energy required for ambulation
Above knee	60%–100% increase in energy required for ambulation
Hip disarticulation	100%–110% increase in energy required for ambulation

Clinical Assessment

The primary preoperative consideration for wound healing is the status of the skin and muscle blood flow. Operative technique, the patient's nutritional status, and the presence of infection also affect wound healing. Clinical judgment by an experienced surgeon accurately predicts healing of a BKA in approximately 80% of cases.²⁸ A palpable pulse at the level immediately proximal to the proposed amputation essentially ensures healing²⁹; however, the converse is not true. Noninvasive arterial testing is the most common adjunctive test used to predict healing of a specific amputation level. Its usefulness is limited when medial sclerosis prevents vessel compression, a condition common in diabetic patients. Because the digital vessels are often spared from this process, digital pressure readings may be helpful in this setting. Transcutaneous oxygen measurement has been shown to predict primary healing, although it is less able to predict failure to heal.^{30,31} It has become more widely available and has supplanted previous less reliable tests that were more limited in availability. Tables 96.3 to 96.6 summarize the results of various preoperative tests to predict wound healing for toe, foot and forefoot, below-knee, and above-knee amputations, respectively.

OPERATIVE TECHNIQUE

General Considerations

Diabetic patients who present septic require adequate fluid resuscitation, broad-spectrum antibiotics (including anaerobic coverage), and an emergent operation. Whereas maintenance of limb length and function is admirable, control of sepsis and wide débridement of all nonviable tissue is essential and potentially lifesaving. All patients require atraumatic tissue handling. Avoid forceps on the skin edge. Excessive skin flaps and dead space are also not desired. Amputations done in the face of active infection are kept open and treated with dressing changes. Consider delayed primary closure in cases where perfusion is intact.

Postoperatively, the limb is elevated to minimize tissue edema and promote healing. Weight bearing on the amputation is delayed until healing is ensured. This patient population requires effective prophylaxis against deep venous thrombosis and venous thromboembolism.

Digital and Ray Amputations

Digital amputations are indicated for some severe and irreducible deformities as well as gangrene or osteomyelitis local-

ized distal to the base of the proximal phalanx. A technique for partial digital amputation is illustrated in Figure 96.2A. The circumferential or racquet-shaped skin incision is made over the distal end of the proximal phalanx and carried down to bone. Nerves and tendons are transected under tension and allowed to retract. The proximal phalanx is divided with bone shears or a power saw and the transected end smoothed with a rongeur. Soft tissue coverage can be performed with either medial/lateral flaps or dorsal/plantar flaps depending on skin tension and viability. The wound is closed only with simple interrupted skin sutures. Judicious use of subcutaneous sutures is advised due to danger of vascular compromise to the small remaining flaps. Non-weight-bearing restrictions or protected weight bearing on the heel only in a rigid soled postoperative shoe or walking boot until the wound heals is recommended.

A ray amputation is indicated when the disease process extends to the metatarsal phalangeal joint. The technique is similar to a digital amputation and is illustrated in Figure 96.2B. A circumferential incision is made at the base of the involved toe and extended proximally on the dorsum of the foot over the metatarsal. The incision is extended to bone. The periosteum is cleared circumferentially and the bone is transected using a power saw at a level that will allow tension-free closure of the wound. In the case of the first or fifth toe, the incision is extended on the medial or lateral aspect of the foot, respectively. Care should be taken to bevel the distal

TABLE 96.5**RESULTS****PREOPERATIVE LEVEL SELECTION: BELOW-KNEE AMPUTATION**

■ SELECTION CRITERIA	■ SUCCESSFUL HEALING, PRIMARY AND SECONDARY PER TOTAL
Empiric	794/974 (82%)
Doppler ankle systolic pressure >30 mm Hg	66/70 (94%)
Doppler calf systolic pressure >50 mm Hg >68 mm Hg	36/36 (100%) 96/97 (99%)

metatarsal stump to minimize any prominence that may lead to skin breakdown with weight bearing or shoe gear wear. Typically, the first metatarsal is beveled from proximal medial to distal lateral and proximal plantar to distal dorsal. Metatarsals 2, 3, and 4 should be beveled from proximal plantar to distal dorsal. The fifth metatarsal is beveled from

proximal lateral to distal medial and proximal plantar to distal dorsal.

In selected cases of neuropathic ulcers, the metatarsal head can be resected leaving the toe intact. A dorsal longitudinal incision is made over the metatarsal bone and the metatarsal head is resected with a power saw. Pulsed lavage and careful soft tissue inspection will help guide appropriate care for the plantar wound (i.e., packing, negative-pressure therapy, or ellipse of wound with closure). The dorsal wound is typically closed unless severe infection is encountered.

Transmetatarsal Amputation

Transmetatarsal amputation (TMA) is a useful procedure that maintains a patient's ability to ambulate without the aid of a prosthesis. It is indicated when the gangrenous or infectious process involves multiple digits or a portion of the forefoot. Care must be taken to plan for the appropriate soft tissue coverage if primary closure is desired. Maximizing the plantar flap is most common, but coverage can also be gained from medial or laterally based flaps and even filleted toe flaps. If adequate soft tissue coverage is not available and a more proximal foot amputation (i.e., Chopart joint amputation) is not desired, then an open amputation through the metatarsal bones can be performed. The wound is allowed to close secondarily or covered with a skin graft. Skin grafts in this position, however, are susceptible to breakdown secondary to the pressure related to ambulation.

The TMA technique is demonstrated in Figure 96.3. A skin incision is made on the dorsum of the foot immediately proximal to the metatarsal heads and extended medially and laterally to a point midway between the plantar and dorsal surfaces. The plantar incision is made along the digital crease and

FIGURE 96.2. A: Digital amputation. A circumferential skin incision is made proximal to the gangrenous process. The proximal phalanx is transected and the soft tissue approximated. B: Metatarsal head resection (ray amputation). A racquet-shaped skin incision is made with the circular component extending circumferentially around the digit and the longitudinal component extending proximal to the metatarsal head. The metatarsal is transected proximal to the head and the soft tissue approximated.

extended diagonally medially and laterally to connect to the dorsal incision. The dorsal incision is deepened to the periosteum, which is cleared with a small periosteal elevator. The metatarsal bones are transected 0.5 to 1.0 cm proximal to the dorsal skin incision. The plantar flap is fashioned by continuing the dissection just superficial to the metatarsal heads. Care is taken to maintain plantar flap thickness. The nerves and tendons are transected sharply under tension and allowed to retract. The plantar flap is rotated anteriorly and assessed for length. Excess tissue is excised sharply and the deep tissue is approximated with absorbable suture. The skin is closed without tension using monofilament suture or skin staples.

Weight bearing is delayed for 1 month to allow adherence of the plantar flap. Either a soft dressing or a short leg cast can be used for a postoperative dressing.

Staging a tendo-Achilles lengthening (TAL) is important to consider following (or at the same time if no infection is present) a partial foot amputation. Ulcer formation at the TMA stump site is often related to equinus formation due to the ensuing flexion/extension imbalance that occurs after resection of the forefoot. A simple triple hemisection percutaneous TAL can effectively lengthen the Achilles and reduce future pressures at the stump site.³² Other tendon-balancing procedures may be needed to control varus and valgus contraction deformities that can develop.

Syme Amputation

The Syme amputation is a foot amputation that preserves limb length and the epiphyseal growth plates and allows occasional ambulation without a prosthesis. It is indicated in cases of extensive foot trauma or other nonviable tissue conditions distal to the hindfoot. The Syme amputation is contraindicated if a supple intact heel pad and a well-vascularized hindfoot tissue flap are not available.

The procedure can be performed in one or two stages, as illustrated in Figure 96.4. The initial steps for both procedures are identical, except that the skin incision for the two-stage procedure is located 1.5 cm more distally. The skin incision for the one-stage procedure extends from the medial to the lateral malleolus in the horizontal and vertical planes. The dorsal incision is extended to the bone, and the tendons are transected under tension. The anterior tibial artery is identified, divided, and suture ligated. The dissection is carried into the tibiotalar joint space as the foot is forcibly plantar flexed. The ligaments are transected and the talus is dislocated. The plantar aspect of the incision is deepened to the calcaneus, and the calcaneus is sharply dissected from the plantar fascia. The plantar fascia is densely adherent and care must be taken to prevent damage to the heel pad, especially at the level of the Achilles tendon. The posterior tibial artery must be preserved,

FIGURE 96.3. A: Skin incision for the transmetatarsal amputation is made on the dorsum of the foot immediately proximal to the metatarsal heads and on the plantar surface within the digital crease. B: Metatarsal heads are transected proximal to the skin incision and separated from the plantar soft tissue flap along a plane adjacent to the bone. C: Plantar soft tissue flap is rotated anteriorly and approximated.

because it perfuses the heel pad. The foot is then removed. The two procedures differ from this point forward.

In the one-stage procedure, the medial and lateral malleoli are transected flush with the tibiotalar joint space, and the heel pad is rotated over the ends of the tibia and fibula. The deep fascial layers are approximated with absorbable suture and the skin is closed with monofilament suture or skin staples. Securing the distal end of the remaining plantar fascia to a small drill hole in the distal anterior tibia will help anchor the plantar flap and reduce posterior migration. In the two-stage procedure, the heel pad is similarly positioned and the wound is closed without further bone transection. In 6 weeks, elliptical incisions are made over the medial and lateral malleoli and the distal ends of the tibia and fibula are transected flush with the ankle joint. In addition, the distal flares of the tibia and fibula are transected, creating the rectangular stump of the two-stage procedure. The wound is closed in a similar fashion. For both procedures, weight bearing is delayed for at least 4 weeks to allow heel pad fixation. A soft dressing or a short leg cast can be used.

Below-knee Amputation

The complications of diabetes and arterial insufficiency constitute most of the indications for below-knee amputations.

Tables 96.5 and 96.6 outline the criteria used to decide between a BKA and an AKA in this setting.

The most common technique, using a long posterior flap, is illustrated in Figure 96.5. When gangrene, wounds, or incisions preclude the use of a posterior flap, equal anteroposterior or sagittal flaps can be used; however, the posterior flap is associated with the highest incidence of primary healing and is thus preferred whenever possible. This higher rate of healing reflects the fact that the posteriorly located gastrocnemius and soleus muscles are supplied by the sural arteries that originate proximal to the knee.

The proposed skin incision is drawn on the leg with a marker. The tibia should be transected 10 cm distal to the tibial tuberosity and the anterior aspect of the skin incision should be 1 cm distal to the site selected for the tibial transection. The anterior incision is extended medially and laterally. The length of the anterior incision should equal two thirds of the circumference of the leg at the proposed level of the tibial transection. The incision is then extended longitudinally along the medial and lateral aspects of the leg. The length of the longitudinal incisions should equal one third of circumference of the leg at the level of the tibial transection. It is prudent to err on the side of making the posterior flap too long and trim excess length at the time of closure. The medial and lateral incisions are connected posteriorly. Curving the transitions of

FIGURE 96.4. A: Skin incision for the one-stage Syme amputation connects the medial and lateral malleoli in both the horizontal and vertical planes. The skin incision for the two-stage procedure is located approximately 1.5 cm further distally. B: Incision is extended into the tibial-talar joint space, and the foot is placed in forced plantar flexion. C: Calcaneus is sharply dissected from the adherent plantar fascia along a plane adjacent to the bone. D: Heel pad is rotated anteriorly and approximated after the calcaneal dissection in the two-stage procedure and after the additional transection of the medial and lateral malleoli in the one-stage procedure. E: Elliptic incisions are made over the medial and lateral malleoli during a second operation for the staged procedure. The medial and lateral malleoli are transected flush with the ankle joint, and the distal flares of the tibia and fibula are removed. F: Two-stage procedure results in a less bulbous, more cosmetically acceptable residual limb.

FIGURE 96.5. A: Skin incision for a below-knee amputation based on a posterior flap is made 11 cm distal to the tibial tuberosity and extended medially and laterally to the midpoint of the calf. The length of the posterior flap is about 2 cm longer than the diameter of the calf at the point of the proximal incision. B: Tibia is transected 1 cm proximal to the skin incision. The fibula is transected an additional 1 cm proximal to the level of the tibial transection, and the posterior calf muscles are incised along the plane of the skin incision. C: Anterior aspect of the tibia is beveled at an angle of about 45 degrees, and the bone edges are filed. D: Posterior flap is rotated anteriorly and approximated.

the incision prevents the accumulation of redundant tissue at the medial and lateral aspects of the completed amputation. The skin incisions should be down to the fascia to allow separation of the skin edges. This step decreases the chance of inadvertent injury to the posterior flap later in the procedure; however, the greater and lesser saphenous veins need to be ligated and transected.

The anterior aspect of the incision is deepened through the periosteum of the tibia. The muscles of the anterior compartment are divided at the level of the skin incision and the anterior tibial neurovascular bundle is identified and suture ligated. The proximal tibia is circumferentially cleared of periosteum, and transected 1 cm proximal to the skin incision. The anterior aspect of the tibia is cut on a 45-degree angle. The fibula is cleared and transected 1 cm proximal to the transected tibia. The bones are divided with either a power-driven reciprocating saw or a manual saw. Regardless, care must be taken to avoid trauma to the anterior skin flap.

The posterior tibial and peroneal neurovascular bundles are identified and suture ligated. The tibia is retracted anteriorly and the posterior musculature is divided along the plane of the longitudinal skin incisions using an amputation knife. Extreme caution must be taken to avoid injury to the skin edges of the posterior flap during this step. Often a scalpel is needed to complete the division of the gastrocnemius tendon distally. The specimen is removed; manual compression achieves temporary hemostasis while the remaining vascular structures are identified and ligated. The posterior tibial nerve is retracted distally, ligated, transected sharply, and allowed to retract. The posterior flap is rotated anteriorly to assess thickness and length. Frequently, the musculature needs to be debulked to allow a tension-free closure. Rough edges of the bones are filed smooth and the wound is irrigated. Bone wax is not used. A closed-system drain may be placed to prevent a hematoma. The end of the tibia is covered and stabilized with the deep posterior musculature using absorbable sutures. The

gastrocnemius fascia is approximated to the anterior fascia using absorbable suture. The subcutaneous tissue is closed with absorbable suture to minimize tension on the skin edges and the skin is closed with monofilament suture or staples.

The length of the BKA may be shortened if required by the infectious or gangrenous process. Although not ideal, a short BKA is functionally superior to an AKA. In the extreme case, the tibia can be transected at the level of the tibial tuberosity and the stump can still be fit with a prosthesis. If a BKA is necessary at this level, the biceps tendon and collateral ligament should be sutured to the tibia, the common peroneal nerve should be transected above the knee, and the fibula should be removed.

In the face of extensive foot infection, an open (guillotine) amputation should be performed as the first part of a staged procedure. A circumferential incision is made in the distal leg just proximal to the malleoli. The fascia is divided, and the tibia and fibula are dissected free. The bones are divided at the level of the skin incision. All major neurovascular bundles are suture ligated and the remaining soft tissue is divided to complete the amputation. Several sutures are placed through the skin and underlying fascia to prevent retraction. The wound is left open and dressed. A negative-pressure dressing may be used and simplifies wound care. A definitive BKA is delayed until the infectious process has resolved, which typically occurs within a week. Ankle disarticulation is an alternative to a guillotine BKA. An incision is made at the level of the ankle joint. Vascular structures are suture ligated. The tendons are divided sharply entering the ankle joint. The capsule is circumferentially incised removing the foot from the leg. The wound is packed open.

Above-knee Amputation

An AKA is indicated for patients requiring an amputation with a fixed-knee contracture, a nonfunctional limb, or insufficient circulation to heal a BKA. Typically, a transverse fish-mouth incision is made in the lower thigh. The initial skin incision should be carried through the subcutaneous tissue to allow the edges to separate. This step will decrease the likelihood of inadvertent injury to the posterior skin flap during transection of the posterior muscle groups. The greater saphenous vein needs to be identified and ligated. The dissection is carried down to the femur, which is cleared using a periosteal elevator to a level 2 to 3 cm proximal to the skin incision. The superficial femoral artery is dissected free and suture ligated. The bone is transected with a reciprocating or manual saw, and the posterior muscle flap is divided with an amputation knife. Manual compression with a laparotomy pad on the newly divided stump will easily control hemorrhage while vessels are identified and ligated or electrocoagulated. The sciatic nerve is identified and placed on gentle traction. It is then highly ligated, sharply divided, and allowed to retract into the wound. The flaps should be power irrigated and hemostasis ensured. The fascia is then closed with absorbable suture. The subcutaneous tissue is closed with absorbable suture to minimize tension on the skin edges and the skin is closed with monofilament suture or staples. Alternative incisions can be made to accommodate surgical wounds. Most AKA wounds will heal even when the femoral pulse is nonpalpable. More proximal thigh amputations are performed when arterial perfusion is in question.

Hip Disarticulation

Lower extremity amputation at the level of the hip is an uncommon operation. The indications include malignancy, trauma, infection, and, rarely, complications of arterial insufficiency. Hip disarticulation performed for an ischemic AKA is

often associated with complications in the absence of revascularization.³³ The technique is well described.

Cryoamputation

Rarely, a patient may require an emergent amputation yet have overwhelming medical problems that preclude any operative intervention. In this situation, a temporizing cryoamputation (aka, medical or physiologic amputation) is indicated.¹⁴ A tourniquet is placed proximal to the infectious or gangrenous process and the extremity is packed in dry ice. This prevents the systemic release of muscle degradation products and allows the required procedure to be delayed while the patient's condition can be stabilized. This technique can be performed at any level on the extremity. Consideration of the level of tourniquet application is extremely important to preserve as much viable tissue as possible and avoid higher levels of limb loss. The dry ice should be placed about 3 inches below the tourniquet to reduce the chance of the "freeze line" extending proximal to the tourniquet. Adequate pain management should always be employed.

It should be noted that the use of cryoamputation constitutes a commitment to eventual surgical amputation (primary or staged). Once initiated, maintenance of the physiologic amputation is vital until definitive surgical removal is possible. As the frozen tissues thaw, a systemic inflammatory response syndrome (SIRS) or sepsis with hemodynamic instability may occur as inflammatory mediators are liberated back into the circulatory system. The ideal timing to proceed to the operating room would be as soon as reasonably possible. However, the literature describes the successful maintenance of this technique over many days if necessary.^{14,34,35}

Other Lower Extremity Amputations

Three additional partial foot amputations have been well described. A Lisfranc amputation is performed at the tarsometatarsal joint level and may be an option if there is inadequate soft tissue coverage for a transmetatarsal amputation.³⁶ A Chopart amputation is performed at the level of the calcaneocuboid–talonavicular bones. Consideration of adding a percutaneous heel cord lengthening with these amputations has been recommended.³⁷ A partial calcanectomy hindfoot amputation has shown good utility for chronic posterior heel wounds and calcaneal osteomyelitis.^{38,39} This amputation involves removal of the posterior body of the calcaneus behind the posterior facet of the subtalar joint. Primary closure is typically possible and patients can ambulate following this procedure using a custom orthotic with a heel filler. Knee disarticulation is a useful amputation for patients with immature growth plates. It is superior to an AKA and allows end weight bearing, improved proprioception, and improved prosthetic control. The required prosthesis is bulky and less cosmetically appealing than that used for a BKA. The technique is well described.⁴⁰ Rotationplasty is an uncommon procedure performed primarily for treatment of osteogenic sarcoma of the thigh.⁴¹ It involves nerve-sparing resection of the femur and knee, 180-degree rotation of the leg, and reattachment of the leg. This results in a functional, sensate foot that can easily be fit with a prosthesis.

Wound Dressings

An important consideration after amputation is the type of wound dressings applied to the stump. Two important factors in the success of an amputation are time to rehabilitation and complete wound healing, both of which are influenced by postoperative wound care.⁴² With transtibial amputations,

there are a number of options, such as soft gauze dressings with elastic wrap, rigid plaster dressings without immediate prosthesis, rigid plaster with immediate postoperative prosthesis, and prefabricated pneumatic postoperative prosthesis. Several studies have compared two or more of these options. End points are not standardized, however, and most studies are not randomized and prospective, making comparisons and meta-analysis difficult.⁴²

Benefits and drawbacks are found for each postoperative option.⁴² Gauze dressings with elastic wrap are simple and low cost and provide good accessibility to evaluate wound healing. On the other hand, they may lead to higher rates of joint contraction and increased time to ambulation, and risk pressure ischemia from poorly placed elastic wrap. Despite these drawbacks, no convincing data show that soft gauze dressings are inferior to other options.^{42,43} A removable knee immobilizer may be used in conjunction with gauze dressings to minimize the risk of joint contracture.

Rigid plaster helps with joint contracture and helps protect the wound from trauma. With addition of a temporary prosthesis, the rigid plaster also promotes early ambulation. The plaster, however, does not provide easy access to evaluate and care for the wound and if not fitted properly will result in sheer stress and thereby break down the wound. Consequently, a level of skill in plaster placement is required of the surgical team to make appropriate and often frequent plaster changes.⁴²

Finally, a prefabricated pneumatic postoperative prosthesis allows early ambulation and weight bearing, easy wound access for examination, prevention of joint contracture, and wound protection. The prosthesis, however, is bulky and up front is more expensive than the simple gauze. Prospective studies have demonstrated statistically fewer postoperative complications with the pneumatic prosthesis and statistically fewer limbs requiring higher revisions.⁴⁴

Complications and Outcome

Morbidity and Mortality. Operative mortality depends on the indication and the level. Mortality rates for major lower extremity amputations in vascular and diabetic patients have been reported to be up to 35%.⁴⁵ Combined mortality rates from multiple series are shown in Table 96.7.⁴⁶ Cardiovascular causes account for two thirds of these deaths, with myocardial infarction responsible for one third.⁴⁶ This data is further supported by recent studies by Sandnes et al.⁴⁷ and Aulivola et al.⁴⁸ Table 96.8 lists known complications after lower extremity amputation.

Long-term survival following major amputation in the vascular population is shown in Table 96.9. The 5-year survival rate is only 37% compared with 85% for age-matched controls.⁴⁹

TABLE 96.7 RESULTS

AMPUTATION MORTALITY

■ CATEGORY	■ PERCENTAGE	■ NUMBER
Below knee	2	25/1,200
Above knee	9	54/609
Diabetic vs. nondiabetic	No difference	
After amputation revision	5.5	12/218

TABLE 96.8 COMPLICATIONS

COMPLICATIONS OF LOWER EXTREMITY AMPUTATIONS

■ SYSTEM	■ COMPLICATION
Cardiac	Arrhythmia, congestive heart failure, myocardial infarction
Pulmonary	Pneumonia, pulmonary embolism
Renal	Renal failure, urinary tract infection
Cerebrovascular	Stroke
Hematologic	Deep venous thrombosis, pulmonary embolism
Wound	Hemorrhage, hematoma, infection, failure to heal

Deep Venous Thrombosis and Pulmonary Embolism

The incidence of deep venous thrombosis following lower extremity amputation ranges from 4% to 38%.^{50–52} Prophylactic measures including subcutaneous heparin, low-molecular-weight heparins, early mobilization, and pneumatic compression devices should be used as indicated.

Stump Complications

Stump complications include nonhealing, infection, hematoma, contractures, ulceration, phantom pain, and trauma. Although most amputations heal primarily, a small percentage do not. Amputation at a more proximal level usually is successful. Postoperative infections complicate 12% to 28% of all amputations, with the percentage higher in cases performed for infection.⁵³ Local wound care with drainage, débridement and dressing changes, and systemic antibiotics should be instituted. Wound hematomas are best treated with prevention. Meticulous hemostasis and avoidance of subcutaneous cavities decrease their incidence. Hematomas should be treated in the operating room with evacuation, irrigation, and closure of the wound.

Joint contractures complicate 1% to 3% of all amputations.^{45,49} These contractures can occur rapidly postoperatively and are best treated by prevention. Rehabilitation specialists and physical therapists should evaluate patients preoperatively. Active and passive range of motion should be

initiated immediately postoperatively. Adequate pain medication, ideally with patient-controlled or epidural anesthesia,^{54,55} is crucial. Pillows and bed positions that result in hip or knee flexion are to be strictly avoided.

Ulcers tend to develop over bony prominences. Poorly fitting prostheses or shoes are the most common causes. Diabetic patients with peripheral neuropathy are especially susceptible to the development of ulcers following toe and limited foot amputations. They can also form on the anterior aspect of AKAs secondary to the disproportional contraction of the hip flexors relative to the hip extensors. Local wound care and bed rest usually lead to healing if the ulcer is superficial. Deep skin ulcers with involvement of the soft tissue and the underlying bone are more complicated. They often suggest borderline perfusion of the stump and require formal revision to a higher level to treat definitively.

Another option in complicated wound closure is negative-pressure wound dressing, which has been used for a wide range of difficult-to-heal lesions. Studies indicate that this dressing technique decreases wound volume, whereas traditional moist gauze dressings do not.⁵⁶ The dressings result in granulation tissue and healing in otherwise difficult tissue beds, such as diabetic foot ulcers⁵⁷ and decubitus pressure ulcers.⁵⁸ In addition to helping contract the size of the wound, negative-pressure dressings also decrease the number and frequency of dressing changes drastically when compared with wet-to-dry dressings. They can also be used following open amputations to help prepare the wound bed for delayed primary closure, skin graft application, or other wound closure techniques.

Neuromas are regenerative nerve tissue that forms in response to transection. They can lead to pain if trapped in the fibrous scar or if irritated by a prosthesis. Proximal nerve division under tension during the original operation decreases the incidence of this complication. Symptomatic neuromas should be treated with proximal resection of the nerve because local excision of the neuroma is rarely adequate.

Some element of phantom extremity pain occurs in nearly all amputations,⁵⁹ although these complaints are not always directed to the treating surgeon. It is necessary to describe these common symptoms to the patient and specifically inquire about their presence. The pain is disabling in 5% to 30%⁶⁰ of patients surveyed. Currently, pain is felt to be a component of a central pain syndrome and unrelated to either a neuroma or the perception of an intact extremity. Although there is no universally effective treatment, Malone⁴⁵ has reported a low incidence with an aggressive rehabilitation program, including immediate prosthetic fitting.

Trauma to a limb following an amputation can convert a healed amputation to a nonhealing wound requiring a more proximal amputation. Perioperatively, patients with a BKA have to be observed closely to prevent attempted ambulation. Diabetic patients with retinopathy should not walk barefoot following toe and foot amputations secondary to the risk that minor trauma may lead to a major wound healing problem.

Additional Amputation

The incidence of future amputation in vascular patients is not insignificant. Snyder et al. evaluated outcomes after forefoot amputations and found that 26% underwent a subsequent forefoot amputation and 37% had a more proximal amputation over 2 years.⁶¹ Cruz et al. demonstrated 17% contralateral amputation in their series.⁶² These dismal figures reflect the systemic nature of the underlying diseases and emphasize the importance of appropriate foot care, patient education, close follow-up, and early intervention.⁶³ A concerted multidisciplinary approach can dramatically decrease the incidence of initial and subsequent lower extremity amputation.⁶⁴

Special Situations

In selected cases, hyperbaric oxygen (HBO) therapy can provide benefit in treating nonhealing amputation sites. Patients require thorough evaluation of their cardiopulmonary status before initiating such treatment. In addition, the treating surgeon has to determine that revascularization is completed or is not indicated. Patients may benefit from treatment if there is a substantial increase in transcutaneous oxygen pressure (TcPO₂) near the wound with administration of 100% oxygen. Daily treatments are typically continued for 30 days. Platelet-derived growth factor (becaplermin, Regranex) is approved for use in the United States and has been effective in the management of diabetic foot ulcers and following open foot amputations or débridements. The wound must be clear of all necrotic tissue before initiating therapy.

REHABILITATION AND PROSTHETIC MANAGEMENT

General Considerations

Rehabilitation must be individualized. For some patients, successful rehabilitation means ambulation on a prosthesis and resumption of an independent lifestyle. For others, success may mean being able to pivot on the contralateral limb to be able to assist with transfer. Ambulating with a prosthesis depends on the physiologic status of the patient. Table 96.2 illustrates the dramatic increase in energy requirement with increasing level of the amputation. As expected, the chance of ambulating on a prosthesis decreases with ascending amputation level. The percentages of diabetic and vascular patients who can ambulate with amputations at various levels are shown in Table 96.10. The likelihood of ambulating postoperatively is inversely related to the patient's age and the length of the rehabilitation process.⁶⁵ Consideration should be given to inpatient rehab immediately after the acute care of the amputation is complete. Not only does this allow strengthening of the upper extremities and improved transfers, but it has also been shown to reduce 1-year mortality in amputees.⁶⁶

Specific Considerations

Digital and Ray Amputations. All patients who were ambulatory preoperatively should be able to achieve their

TABLE 96.10 RESULTS

AMBULATION AFTER LOWER EXTREMITY AMPUTATION FOR DIABETES OR OCCLUSIVE DISEASE

■ AMPUTATION LEVEL	■ POSTOPERATIVE AMBULATION (%)
Digit or ray	100
Transmetatarsal	100
Syme amputation	90–100
Below knee	75
Above knee	39
Hip disarticulation	<100

From Frang RD, Taylor LM, Porter JM. Amputations. In: Porter JM, Taylor LM, eds. *Basic Data Underlying Clinical Decision Making in Vascular Surgery*. St. Louis, MO: Quality Medical; 1994:155, with permission.

preoperative functional status following a digital or ray amputation. The first digit and metatarsal head are important for weight bearing and for power. A shoe orthosis should effectively compensate for these functions when the patient has some training.

The most important component of postoperative rehabilitation for patients following a digital or ray amputation is education. The rate of repeat amputation (other toe, more proximal level, contralateral limb) is extremely high. Several studies have indicated that the rate of repeat amputation is diminished with a coordinated education program.^{67,68}

Transmetatarsal Amputation. A transmetatarsal amputation minimally increases the energy requirement of ambulation; therefore, postoperative ambulation is expected following successful healing. The absence of the toes and metatarsal heads results in the loss of some forward thrust during the push-off phase of ambulation. This deficit can be overcome with either a steel shank or a rigid, roller-soled shoe. The void in the distal shoe is filled with an insert.

Syme Amputation. The prognosis for return to bipedal ambulation following a Syme amputation is excellent. The required energy expenditure is only 10% more than baseline.⁶⁹ A significant advantage of this amputation is the ability to ambulate on the stump with only a cup slipper. Even though this activity is permitted on only a limited basis in the home, it is much more convenient for the patient, especially when arising at night. For routine activity the patient uses a prosthesis composed of a nonmotion foot attached to a leg shaft. The shaft has a cutout on the medial aspect to allow passage of the flared distal end of the stump. The configuration of the distal end of the stump results in a bulbous ankle, which is less aesthetically pleasing than the typical below-knee prosthesis.

Below-knee Amputation. The rehabilitation potential following a BKA is very good. Even when the indication for amputation is arterial insufficiency, approximately 75% of patients are able to ambulate with a prosthesis.⁴⁶ Multiple design options are available; however, the patellar tendon and the medial and lateral tibial flares are the weight-bearing surfaces for most prostheses. A variety of foot designs are possible to permit extension, flexion, rotation, and energy storage.

Above-knee Amputation. Ambulation on an above-knee prosthesis is achieved by less than 40% of patients with arterial insufficiency.⁴⁶ In this patient population, the rate of ambulation on bilateral above-knee prostheses is less than 10%.⁷⁰ Most above-knee prostheses use the ischial tuberosity as the primary weight-bearing surface and are secured either by a belt or a suction socket. For younger patients, a suction socket works well. Patients with groin scars from previous revascularization attempts may benefit from a belt mechanism. The knee design depends on the patient's general condition and thigh strength. A knee that engages during the stance phase of gait is more stable and is frequently used in older patients.

CHAPTER 97 ■ PATHOGENESIS OF ANEURYSMS

B. TIMOTHY BAXTER AND G. MATTHEW LONGO

KEY POINTS

- 1 The principle risk factors for abdominal aortic aneurysm (AAA) are smoking, increasing age, male gender, and family history of AAA.
- 2 Population studies reveal a strong genetic predisposition to AAA formation, the mechanism of which is currently unknown.
- 3 Chronic inflammation, macrophages in particular, play a key role in the degenerative process.
- 4 AAAs are the result of aortic wall degeneration and defective aortic wall remodeling.
- 5 Digestion of elastin and collagen by proteolytic enzymes, such as the matrix metalloproteinases, is crucial to aneurysm formation.
- 6 Structural and hemodynamic factors unique to the infrarenal abdominal aorta most likely play a role in aneurysm pathogenesis.

An aneurysm is a permanent, localized dilation encompassing all three layers of a blood vessel wall. The Committee on Reporting Standards of the major North American vascular societies more precisely defines an aneurysm as a 50% increase in the diameter of a vessel in comparison with its expected normal diameter.¹ Aneurysms are usually classified based on their etiology and anatomic location. The most common etiology of an aneurysm is vessel wall degeneration. Other less common causes include infection, poststenotic

dilation, trauma, arteritis, and various connective tissue defects (e.g., the high incidence of thoracic aneurysms in Marfan syndrome). Despite the occurrence of aneurysms throughout the arterial tree, the predominant extracranial location for aneurysms is the infrarenal aorta. Intracranial aneurysms, although common, appear to be etiologically distinct from extracranial aneurysms. This chapter focuses on the pathogenesis of the degenerative, infrarenal, abdominal aortic aneurysm (AAA).

CLINICAL RISK FACTORS

1 Large-scale studies have shown that patients with AAA possess many of the same risk factors as those who develop atherosclerosis. Increasing age, male gender, and smoking are the three chief risk factors for AAA recently identified within the Aneurysm Detection and Management (ADAM) cohort.² Of all the risk factors implicated in this cohort, the strongest modifiable risk factor appeared to be smoking. Although not all studies of AAA concur, other clinical features associated with aneurysms include hypertension, the presence of coronary artery disease, hyperlipidemia, and chronic obstructive pulmonary disease.³⁻⁹

Abdominal Aortic Aneurysm and Atherosclerosis

Until recently, degenerative AAAs were usually referred to as *atherosclerotic* because of the strong clinical and histopathologic associations between the two disease processes. AAA and atherosclerosis share some of the same clinical risk factors, and atherosclerotic plaque is almost always present in resected aneurysm wall.¹⁰ Some arteries are also known to undergo compensatory remodeling in response to atherosclerotic luminal narrowing.¹¹ Furthermore, in human autopsy studies, increasing amounts of atherosclerotic plaque in the infrarenal aorta were associated with localized aortic dilation and thinning of the aortic media.^{12,13}

Animal experiments lend support to the hypothesis that AAA may be caused by atherosclerosis. In monkeys, Zarins et al.¹⁴ demonstrated that withdrawal of an atherogenic diet resulted in aortic atherosclerotic plaque regression and an associated development of AAAs. In another model primarily used to study atherosclerosis, transgenic mice with apolipoprotein E deficiency were found to spontaneously develop aortic aneurysms.¹⁵ This characteristic can be augmented by giving prolonged subcutaneous infusions of angiotensin II, which has many effects including increases in blood pressure.¹⁶ In addition, recent work has identified a sequence on 9p21 that is associated with a clinical phenotype of AAA and myocardial infarction providing evidence of a common etiologic factor in some individuals with AAA.

Although atherosclerosis may appear to be directly linked with AAA, other evidence suggests that AAA may be its own distinct pathologic process. In 1980, Tilson and Stansel¹⁷ pointed out four important clinical differences seen in groups of AAA and aortic occlusive disease patients. They observed that AAA patients (a) exhibit a higher ratio of men to women, (b) are 10 years older on average, (c) rarely manifest symptoms of lower extremity vascular insufficiency, and (d) rarely experience problems with late graft patency compared with the aortic occlusive disease patients. In addition to these observations, multiple studies have also failed to show a consistent, positive association linking AAA with diabetes mellitus, one of the principle modifiable risk factors for atherosclerosis.²⁻⁴ In fact, the aforementioned ADAM cohort trial found a negative relationship between AAA and diabetes mellitus.

Examination of pathologic specimens reveals histologic differences as well. A transmural process is seen with AAA; however, atherosclerosis is mainly confined with erosion into the media in advanced cases. Some researchers have proposed that atherosclerosis may even be an incidental finding in AAA, citing specimens obtained from poststenotic and syphilitic aneurysms that can show atherosclerotic changes as well.¹⁸

In summary, it appears that the development of AAA is not simply the end result of the atherosclerotic process. Most likely, other factors of equal or greater importance are influencing aneurysm formation. Although the potential role of

atherosclerosis in initiating a local inflammatory process that could lead to AAA in susceptible individuals should not be dismissed, other avenues of research aimed at sorting out the inflammatory response that leads to this susceptibility may prove to be more fruitful in understanding the pathogenesis of AAA. Identification of the protein(s) encoded by the sequence variant in 9p21 may provide critical new insight into the relationship between AAA and atherosclerosis.

CLINICAL AND BASIC SCIENCE RESEARCH IN ABDOMINAL AORTIC ANEURYSM PATHOGENESIS

Abdominal Aortic Aneurysm as a Distinct Pathologic Entity

Recognizing AAA as a distinct pathologic entity with significant morbidity, mortality, and health care costs, the National Heart, Lung, and Blood Institute has sponsored efforts to further understand its pathogenesis. These efforts are focused on four areas: (a) molecular genetics, (b) inflammation and immune responses, (c) proteolytic degradation of the aortic wall connective tissue, and (d) biomechanical wall stress.¹⁹ The remainder of this chapter highlights past and current research in each of these four areas.

Challenges in Aneurysm Research

Before a discussion of AAA research can be fully understood and appreciated, there are two important problems that must be considered. The first is that almost all of the human AAA tissue available for study is sampled late in the course of the disease. The early changes in the human aorta during AAA pathogenesis are essentially unknown and can only be approximated through the use of animal models. The second problem is the lack of a single, well-accepted animal model that reproduces the entire spectrum of pathology found in human AAA. Currently, there are a variety of animal models, each of which develops an aneurysm through a different inciting mechanism. Although many of the models and even late-stage human AAA disease seem to ultimately converge to similar end-stage processes, the events leading to the end-stage disease may in fact be very different. Consequently, all AAA research should be evaluated within the context of these two problems and the limitations of this research should be recognized.

MOLECULAR GENETICS

The study of the genetics of AAA serves two purposes. The first is that by locating and characterizing genes suspected in AAA pathogenesis, investigators may uncover additional pathways for more detailed study. These pathways may also provide potential new targets for pharmacologic intervention. The second, and perhaps most important, purpose is to develop a means for genetic testing to help identify patients at risk for developing AAA early in the course of the disease.

2 Although clinicians treating large numbers of patients with AAA were undoubtedly aware of clusters of aneurysms within families, Clifton²⁰ was the first to describe three affected siblings in 1977. Data supporting this observation did not appear until 7 years later, when Tilson and Seashore²¹ described 50 families with more than one affected member. In 1986, Johansen and Koepsell²² reported the incidence of AAA at 19% among first-degree relatives of matched controls. A more recent study examining first-degree relatives

using ultrasonography corroborated these findings, with 18% of affected siblings older than age 60 years harboring AAAs.²³

Although these studies demonstrated a familial tendency to develop AAA, they did not use genetic models to determine the specific inheritance pattern of AAA. Two of the more conclusive studies to date have used segregation analyses of large pedigrees and both have concluded that the genetic transmission of AAA is best explained by a single gene rather than by multiple factors. However, these studies do not agree on whether the gene inheritance is recessive²⁴ or dominant.²⁵ In contrast, Kuivaniemi et al.²⁶ published their pedigree analysis of 233 families with at least two affected members in 2003. They concluded that AAA is a multifactorial disorder without a single inheritance mode.

In addition to traditional pedigree analysis, new techniques in molecular biology and computer technology have become available to help investigators study the genetic aspects of AAA formation. Two studies using complementary DNA microarrays analyzed the gene expression profiles of human AAA tissue compared to normal and atherosclerotic aortas. AAA tissue demonstrated a pattern showing chronic inflammation, smooth muscle cell depletion, atherosclerosis, and extracellular matrix degradation that was significantly different from the normal aortas.^{27,28} Another study using whole genome scanning and linkage analysis of 36 AAA families found possible susceptibility loci on chromosomes 4 and 19, recommending further study of nearby candidate genes.²⁹

In searching for a gene that might explain AAA, considerable work has focused on the genes regulating matrix protein metabolism, inflammation, and immune function. With the exception of rare cases of collagen mutations,³⁰ no known mutations in matrix proteins can account for the majority of AAAs.¹⁹ Helgadottir et al.^{30a} have recently identified a sequence variant on 9p21 associated with a complex of myocardial infarction, intracranial aneurysm, and AAA. Research has implicated a multitude of polymorphisms in protease, cytokine, and other immunoregulatory genes thought to be associated with AAA (Table 97.1). However, most of these studies are small and lack the statistical power to provide definitive information, so the contribution of each factor to AAA pathogenesis remains to be clarified. Given the multifactorial nature of AAA, it is possible and even likely that a combination of polymorphisms may be interacting to bring about the AAA phenotype. If so, new analytical approaches will be required to identify these combinations.

Gender differences in AAA offer perhaps the most obvious clinical risk factor associated with an increased incidence of AAAs. Lederle et al. as part of the ADAM trial documented that female gender was considered a negative risk factor for developing a small AAA (odds ratio [OR] 0.47 [confidence interval (CI) 0.32–0.69] for aortic diameter (AD) 3.0–3.9 cm, OR 0.18 [CI 0.07–0.48] for AD >4.0 cm).¹ In contrast, the prevalence of AAAs among males older than 50 years is four to five times greater than age-matched females.² After analyzing population-based screening studies, Bengtsson et al. demonstrated that AAAs also develop 10 to 15 years later in women.⁸ Speculation as to why this occurs may be due to decreased circulating levels of estrogen in postmenopausal women, as has been suggested by studies in rodents.

INFLAMMATION AND IMMUNE RESPONSES

Importance of Inflammation

These cells are typically located throughout the intima, media, and adventitia, and in extreme cases produce what is termed *inflammatory AAA*. In contrast to the panmural inflammation of AAA, the microscopic appearance of an atherosclerotic aorta shows an infiltrate of T cells and macrophages located within the intima and media.³³ In comparing larger versus smaller AAAs, Freestone et al.³⁴ found that as aneurysm size increased, so did the intensity of the inflammatory cell infiltrate.

Animal models of AAA confirm the importance of inflammation in the aorta during aneurysm formation. In the elastase infusion model, transient infusion of the infrarenal rat aorta with porcine pancreatic elastase immediately renders the aorta slightly larger than its preperfusion diameter through the mechanical disruption of the elastic lamellae. The aorta then remains stable in size for nearly 3 days. When examined after 3 days, however, a 300% increase in size is seen with a concurrent inflammatory cell infiltrate.³⁵ This model has been adapted to mice, with the inflammation and secondary enlargement occurring closer to 2 weeks following elastase infusion.³⁶ A second commonly used mouse model employing the periaortic application of calcium chloride also shows an intense inflammatory cell infiltrate preceding aortic enlargement.³⁷ Further evidence that invading inflammatory cells play a key role in AAA progression comes again from the elastase infusion model. In these experiments, rats treated with either cyclosporine or methylprednisolone failed to develop aortic inflammation and subsequently did not develop AAAs in comparison to placebo-treated control rats.³⁸

Recruitment of the Inflammatory Cell Infiltrate

The stimulus for the recruitment of the inflammatory cells into the aorta is currently unknown and is an area of ongoing research. The elastin degradation product hypothesis suggests that as the elastin in the aortic wall breaks down, specific epitopes are exposed generating an immune response with subsequent inflammatory cell invasion. Supporting experimental evidence comes from Hance et al.,³⁹ who studied soluble elastin degradation fragments from human AAA tissue. They found that these peptides are able to attract mononuclear phagocytes in vitro through a specific interaction with a 67-kD elastin-binding protein receptor on the phagocytes. Elastin degradation products have also been found to induce angiogenesis in the adventitia of rat aortas.⁴⁰ What remains to be explained is the inciting event leading to elastin breakdown and whether these peptides initiate or help amplify the immune response in AAAs.

Studies of human AAA tissue reveal characteristics consistent with an autoimmune process, namely large amounts of immunoglobulin G⁴¹ and the presence of plasma cells.³¹ Additionally, a proposed autoantigen has been identified and characterized by Gregory et al.⁴² It is a 40-kD protein similar to an extracellular matrix component that specifically binds to antibodies isolated from human AAA. However, two more recent studies have cast doubt on this autoimmune hypothesis, characterizing the immune response in AAA tissue as relatively nonspecific.^{43,44}

Infection with *Chlamydia pneumoniae* has been suggested as a possible contributor in the formation of AAA. In one early study, investigators found that chlamydial antigens were present in a majority of human AAA tissue samples compared with healthy control aortas.⁴⁵ Subsequent studies have confirmed that chlamydia, or chlamydial antigens, are frequently present in AAA tissue.^{46,47} In another study by Tambiah and Powell⁴⁸ using a rabbit model of AAA, topical treatment of the aorta with chlamydial antigens enhanced aneurysm formation through a process that could be attenuated by treatment with azithromycin. In this instance, the mere presence of the

3 Histologic examination of human AAA tissue demonstrates an inflammatory cell infiltrate consisting of T cells, B cells, dendritic cells, plasma cells, natural killer cells, and macrophages.^{31–33}

chlamydial antigens was sufficient to enhance aneurysm development without active infection, leading the investigators to suggest that azithromycin most likely worked through an anti-inflammatory mechanism. Altogether, however, considering the high prevalence of chlamydial infection in the general population,⁴⁹ strong evidence of specificity for AAA is currently lacking.

Another possible recruitment mechanism involves the action of chemokines, a related family of low-molecular-weight cytokines that control leukocyte trafficking. Compared with controls, human AAA tissue contains greater amounts of the chemokines interleukin-8 (IL-8) and monocyte chemoattractant protein-1.⁵⁰ In mice, work using the elastase infusion model has demonstrated an increased production of the chemokine monocyte chemoattractant protein-1 and chemokines regulated on activation (normal T-cell expressed and secreted) in aneurysmal tissue. Notably, the expression of these chemokines by the aortic smooth muscle cells preceded the influx of inflammatory cells during the experimental AAA development.⁵¹ Mactaggart et al.^{51a} have investigated the role of three different chemokine receptors using a murine AAA model and mice with targeted deletions of these receptors. CCR2, but not CCR5 or CXCR3, was found to be the critical chemokine receptor for aneurysm formation.

Cytokines and Abdominal Aortic Aneurysm

Once inflammatory cells are present in the aorta, they can produce a multitude of effects. One of the most critical functions is that of coordination and direction of the ongoing immune response. This effect is achieved through the action of cytokines, which can be produced both by invading inflammatory cells and by resident mesenchymal cells. The cytokine profile of human AAA tissue has been extensively examined. Studies of homogenized AAA tissue, as well as AAA tissue culture explants, have found overexpression of proinflammatory cytokines, such as tumor necrosis factor- α , IL-6, and IL-1 β .^{52,53} The Th1 cytokine interferon- γ (IFN- γ) in conjunction with other Th1 cytokines, IL-2, IL-12, and IL-18,⁴ has also been implicated in human AAA,⁵² and elevated circulating levels of IFN- γ appear to correlate with more rapid aneurysm expansion.⁵⁴ Furthermore, a recent study using the calcium chloride AAA model in mice demonstrated that transgenic mice deficient in IFN- γ were unable to produce aneurysms. The ability to generate aneurysms was regained with the transplantation of splenocytes capable of producing IFN- γ .⁵⁵

These findings contrast with recent work implicating the Th2 cytokine response. Schonbeck et al.⁵⁶ examined the cytokine profile of human AAA tissue and found no evidence for Th1 or IFN- γ pathway activation, but rather an abundance of IL-4, IL-5, and IL-10, all Th2 cytokines.⁵⁶ Extending these observations into an animal model, researchers transplanted wild-type mouse aortas into mice deficient in IFN- γ receptors. Despite the absence of IFN- γ receptors in all cells save for the transplanted aorta, these chimeric mice were able to form large aneurysms. Upon treatment with anti-IL-4 antibody, however, these transplanted mice were unable to form aneurysms, a finding confirmed in IL-4 knockout mice.⁵⁷ These findings had suggested that invading inflammatory cells depend on Th2 signaling pathways for aneurysm development. Recent studies have discovered the presence of natural killer (NK) and natural killer T (NKT) cells present within the media and adventitia of abdominal aortic aneurysms. These cells display a Th0 cytokine profile, and thus can produce both Th1 and Th2 cytokines. Based on this finding, it is possible that NK and NKT cells may play a role in the pathogenesis of aortic aneurysms rather than a Th2-specific cytokine response.^{56,57}

Smooth Muscle Cell Depletion

The presence of inflammatory cells and the cytokine environments they produce are thought to be responsible for another unique feature found in AAA—decreased medial smooth muscle cell density. Histologic examination of AAA specimens reveal a paucity of medial smooth muscle cells as well as fragmentation of the remaining vascular smooth muscle cells compared with normal and atherosclerotic aortas.^{58,59} In addition, many of the smooth muscle cells present show features consistent with apoptosis.⁵⁸ The significance of these findings is clear, as smooth muscle cells are primarily responsible for the deposition and maintenance of the aorta's normal extracellular matrix. This concept was recently illustrated using an aortic xenograft rat model, where seeding of the graft with vascular smooth muscle cells resulted in protection of the graft from inflammation, proteolysis, and aneurysm formation.⁶⁰

Role of Prostaglandins

Several studies have examined the role of prostaglandin E₂ (PGE₂) in aneurysm formation. In these studies, researchers have found an increased expression of cyclooxygenase-2 (COX-2) localizing primarily to infiltrating macrophages. COX-2 is thought to be responsible for the increased PGE₂ levels found in both human aneurysm tissue and conditioned media from aortic tissue culture.^{61,62} PGE₂ may be important in aneurysm pathogenesis by virtue of its ability to alter matrix metalloproteinase (MMP) activity, cytokine expression, and smooth muscle cell viability. Indomethacin, a nonspecific cyclooxygenase inhibitor, decreases PGE₂ in aortic tissue culture and also has been shown to decrease the size of experimental aneurysms in the rat elastase infusion model.⁶³

Oxidative Stress

Inflammatory cells can also be a significant source of reactive oxygen species. These toxic substances, which may also be produced by mesenchymal cells and endothelial cells, are capable of inducing apoptosis of smooth muscle cells and activating proteases.^{64,65} Miller et al.⁶⁶ have shown that reactive oxygen species and evidence of oxidative damage are increased in human AAA tissue. In rats, using the elastase infusion model, investigators have shown that genes associated with oxidative stress, such as those coding inducible nitric oxide synthase and heme oxygenase, are upregulated during aneurysm development.⁶⁷ In addition, using the same rat model, inhibition of inducible nitric oxide synthase, one of many enzymes capable of producing nitric oxide, attenuated aneurysm development.⁶⁸ Researchers studying mice using the elastase infusion model have confirmed that elevated inducible nitric oxide synthase expression and nitric oxide-mediated tissue damage are seen during aneurysm formation. However, this same study also found that mice lacking the gene for inducible nitric oxide synthase were able to form aneurysms in a similar manner to controls, casting doubt on the importance of this enzyme in AAA pathogenesis.⁶⁹ Xiong et al.^{69a} recently demonstrated that inducible nitric oxide synthase-null mice were resistant to aneurysm formation using the calcium chloride aneurysm model. Among the pathways that generate reactive oxygen species, the nicotinamide adenine dinucleotide phosphate oxidase pathway was found to be the critical pathway.

Protease Production

Finally, and possibly most importantly, invading inflammatory cells are capable of producing proteases, or inducing

surrounding mesenchymal cells to produce proteases, that have the ability to destroy the extracellular matrix structures necessary for maintaining aortic wall integrity. This concept has been extensively studied and is another one of the main categories of AAA pathogenesis research.

PROTEOLYTIC DEGRADATION OF AORTIC WALL CONNECTIVE TISSUE

4 The two principle functions of the aorta, blood transport and
5 transmission of pulsatile energy, demand both tensile strength and elasticity in its structure. These properties are provided mainly by collagen and elastin, two connective tissue proteins synthesized and maintained primarily by resident mesenchymal cells in the aortic wall. Because the normal structure and function of the aorta are so dependent upon these two proteins, the study of elastin, collagen, and their metabolism has provided valuable insight into the pathogenesis of AAA.

Collagen

Collagen is present both in the aortic media and the adventitia, and is chiefly responsible for imparting tensile strength to the aorta.⁷⁰ The predominant forms of collagen in the aorta are types I and III.⁷¹ When comparing human AAA tissue with normal control aortas and aortas with occlusive disease, it is clear that the expression of both type I and type III collagens are increased in aneurysmal tissue.^{72,73} Moreover, the mass of collagen has been shown to increase progressively with increasing aneurysm size.⁷⁴ This increased expression, which appears to be regulated by a soluble tissue factor,⁷⁴ localizes to adventitial fibroblasts, medial smooth muscle cells adjacent to inflammatory infiltrates, and transformed myofibroblasts within atherosclerotic plaque.⁷⁵ Further evidence of increased collagen metabolism in AAA was demonstrated by finding elevated plasma levels of the aminoterminal propeptides of type III procollagen, a marker of type III collagen turnover, in AAA patients compared to controls.⁷⁶ Mutations in type III collagen have been identified and linked to AAA³⁰; however, these mutations are rarely the cause of degenerative AAA.¹⁹

Elastin

Elastin, which comprises approximately 50% of the dry weight of the normal aorta,⁷⁷ is the other major aortic connective tissue protein and is responsible for the aorta's viscous and elastic properties.⁷⁸ It is synthesized and secreted as a soluble monomer, tropoelastin, which is organized and cross-linked into insoluble fibers on a preformed scaffold of microfibrillar proteins forming the medial lamellae.⁷⁹ The unique structure of elastin fibers confers resistance to proteolytic degradation and the half-life of elastin in human tissues is measured in decades.⁸⁰ Most elastin is thought to be produced by the early postnatal period, although elastin production does continue at very low levels into adulthood.⁷³ Recently, Krettek et al.⁸¹ identified macrophages within human AAA tissue as a source of additional tropoelastin synthesis. This elastogenesis appeared ineffective, however, as markers of mature, organized elastin were greatly diminished.

In examining histologic sections of human AAA tissue, one of the most striking features is the fragmentation of the medial lamellae and the decreased concentration of elastin.^{82,83} Para-

doxically, biochemical studies looking at the absolute mass of elastin in aneurysmal aortas compared with normal aortas have shown larger amounts of elastin in the diseased tissue.^{84,85} This finding is most likely explained by poor uptake of stain by the newly synthesized and unorganized elastin and also by the redistribution of the elastin over a larger aortic diameter. Nevertheless, despite an overall increase in elastin content, the increase does not keep pace with aortic expansion and its concentration is markedly decreased relative to that of collagen.^{82,85} This effect results in increased stiffness in the aneurysmal aortic wall.

Proteolytic Enzymes

Because disruption of collagen and elastin is necessary for and well documented in AAA pathogenesis, investigators have focused intensely on studying the enzymes capable of degrading them. In the early 1980s, researchers began studying the proteolytic activity within human AAA tissue.^{86–88} Since then, numerous studies have demonstrated the importance of the enzymatic degradation of the aortic wall in the development of AAA (Table 97.2).¹²⁴ Although there are many enzymes capable of degrading these proteins in vivo, particular emphasis has been placed on the study of metalloproteinases.

Matrix Metalloproteinases. Matrix metalloproteinases (MMPs) are a family of structurally related enzymes that are capable of digesting the various components of the extracellular matrix. They are produced by most of the cell types native to the aorta, such as endothelial cells, smooth muscle cells, and adventitial fibroblasts, and are also produced by invading inflammatory cells, such as macrophages. The normal physiologic function of these enzymes is thought to be primarily extracellular matrix remodeling, although participation in other functions, such as cell motility and cell signaling, are also known.⁸⁹ Most MMPs are secreted from cells in a proenzyme form and require some form of processing to become fully activated. Other MMPs are anchored to cell surfaces to help concentrate their activities close to the cell. Regulation of MMP synthesis and activity occurs through a number of mechanisms. MMP synthesis is primarily regulated at the level of transcription. Activity level may be regulated by the processing of the proenzyme form to its active form. Endogenous inhibitors (tissue inhibitors of metalloproteinases) and interaction with specific extracellular matrix components can also affect activity.⁹⁰ Dysregulation of MMP activity has been linked with not only vascular disease but also malignancy, rheumatoid arthritis, and a host of other pathologic conditions.

Matrix Metalloproteinase 9. MMP-9, also known as *gelatinase B*, is one of the most extensively studied MMPs within AAA research. MMP-9 has the capacity to degrade both elastin and partially hydrolyzed collagen. Using zymography and immunohistochemistry, studies of human AAA tissue have demonstrated increased amounts of MMP-9 compared with control tissue.⁹¹ Furthermore, this MMP-9 localizes to areas surrounding infiltrating macrophages in the aortic wall. Using the elastase infusion model in mice, Pyo et al.³⁶ showed that mice lacking the gene for MMP-9 were resistant to AAA formation. In addition, they were able to show that the key source of MMP-9 was in fact the infiltrating macrophage, as infusion of bone marrow cells from mice with the MMP-9 gene into the MMP-9 knockout mice permitted aneurysm formation.

Matrix Metalloproteinase 2. MMP-2, also known as *gelatinase A*, is another MMP found to be important in AAA pathogenesis. MMP-2 has the capacity to degrade elastin, but unlike MMP-9, MMP-2 can degrade intact fibrillar collagen.⁹² MMP-2

AAA, abdominal aortic aneurysm; MMP, matrix metalloproteinase; SMC, smooth muscle cell; TIMP, tissue inhibitors of metalloproteinases. Adapted from Ailawadi G, Eliason JL, Upchurch GR Jr. Current concepts in the pathogenesis of abdominal aortic aneurysm. *J Vasc Surg* 2003;38:584-588.¹²⁴

also differs from MMP-9 in that processing of MMP-2 to its activated form requires the presence of other membrane-bound MMPs.⁸⁹ Like MMP-9, MMP-2 levels and activity have been found to be greater in human AAA tissue compared with controls^{93,94}; however, whereas MMP-9 is typically not present in disease-free aortas,⁹¹ MMP-2 is constitutively produced by resident mesenchymal cells even in histologically normal aortas.⁹³ Confirmation of the importance of MMP-2 to AAA development has come from the calcium chloride mouse model of AAA. In this study, Longo et al.³⁷ were able to show that the targeted deletion of the MMP-2 gene inhibited AAA formation and that the key source of MMP-2 production was not invading inflammatory cells but resident mesenchymal cells. The stimulus for the increased production and activation of MMP-2 in aneurysmal aortas remains unknown.

Other Matrix Metalloproteinases. MMP-12, also referred to as *macrophage elastase*, is also elevated in human AAA tissue

compared with controls. Importantly, immunohistochemical analysis has localized the enzyme to areas of elastin destruction.⁹⁵ In contrast to MMP-9 and MMP-2, however, MMP-12 has not been shown to be absolutely required for aneurysm generation in knockout mice.³⁶ Levels of other MMPs are altered in AAA as well, but current studies have not documented a definitive role for these enzymes in AAA development.

Other Proteases. In addition to MMPs, other proteases and their endogenous inhibitors have been suggested as potential contributors to AAA pathogenesis. Cystatin C, an endogenous inhibitor of cysteine proteases, appears to be reduced in human AAA tissue.⁹⁶ Serine proteases, particularly neutrophil elastase, have been hypothesized to play a role in AAA formation because of their potent elastase activities. However, there is currently no supporting experimental evidence. Other serine proteases, such as those from the plasminogen activator family, have been shown to play a role in AAA formation,

AR blockers	48, 50	Animal data	C	IIb

ACE, angiotensin-converting enzyme; AR, angiotensin receptor.
^aInhibition at 6 and 12 months following 3 months of treatment.

although the main pathogenic mechanism involving these enzymes appears to be activation of MMPs.⁹⁷

Potential Medical Therapy. In addition to adding to the basic knowledge of AAA pathogenesis, the study of MMPs has also led to the realization that inhibition of their activity may prevent or slow aneurysm growth. Tetracycline and its derivatives are potent inhibitors of MMPs *in vitro*⁹⁸ and in animal studies have inhibited aneurysm expansion.^{99,100} Small trials in human AAA patients have been performed^{101,102}; however, definitive evidence for their efficacy awaits large-scale randomized trials. Thus, medical therapy for the treatment of AAA, especially smaller aneurysms, may very well be an alternative to surgical therapy in the future.

Overall, four major classes of drugs have been studied as therapies for decreasing aneurysm growth rates: beta-blockers, antihypertensives (diuretics, angiotensin-converting enzyme inhibitors, calcium channel blockers), antibiotics with inhibitory function on MMPs, and anti-inflammatory agents (statins, nonsteroidal anti-inflammatory drugs) (Table 97.3). A meta-analysis of the available cohort studies suggests that beta-blockers and statins may reduce AAA growth rates. However, the results of three randomized control trials for beta-blockers do not support the conclusion that beta-blockers have an inhibitory effect on AAA growth rates.⁶ To date, there are no randomized control trials investigating statins and AAA growth.⁷ The human trials investigating the results of antibiotics inhibiting MMPs exhibit promise; however, they were not powered adequately to demonstrate statistical significance. Interestingly, recent data do indicate that statins also possess an inhibitory effect on MMPs, in addition to anti-inflammatory properties.⁸

BIOMECHANICAL WALL STRESS

Unique Conditions in the Infrarenal Aorta

- 6 The infrarenal aorta is subjected to unique hemodynamic flow patterns and also possesses specific structural characteristics that are thought to predispose it toward aneurysm formation. Reflected pressure waves from the aortic bifurcation and the presence of large renal and splanchnic artery takeoffs result in disturbed flow patterns.¹⁰³ The elastin-to-collagen ratio decreases distally, translating into increased stiffness in this section of the aorta.¹⁰⁴ In addition, the absence of vasa vasorum in the normal abdominal aortic media¹⁰⁵ and the presence of a thick intraluminal thrombus are thought to impair oxygen and nutrient delivery to the aneurysmal aorta.¹⁰⁶ All of these

observations are plausible reasons for the development and progression of disease in the infrarenal aorta.

Aortic Wall Stress

Stress on the aortic wall is one of the key factors involved in the rupture of AAAs. Peak wall stress has been demonstrated as superior to maximal diameter for predicting the risks of AAA rupture.⁹ The law of Laplace is often used to explain the propensity for larger aneurysms to rupture because it predicts wall tension to be directly proportional to the product of the radius of a tubular, thin-walled structure (AAA diameter) and its intraluminal pressure (patient blood pressure). This explanation may be an oversimplification, however, because AAAs are often asymmetric and thick walled with major and minor wall curvatures,¹⁰ and become more spherical in shape as their size increases.¹⁰⁷ Because of these factors, researchers are developing improved methods to help determine patterns of stress on the aneurysmal aortic wall, as well as the effect of stress on the pathogenesis of AAA.

Raghavan et al.¹⁰⁸ have recently used a method termed *finite element analysis* to noninvasively determine AAA wall stress distribution and AAA rupture risk. Application of this method comparing calculated stress values obtained from patients near the time of AAA rupture with patients who have size-matched electively repaired AAA showed significantly elevated stress values in the ruptured AAA group.¹⁰⁹ Although still investigational, these methods could have an important impact on determining the indications for operative repair of AAAs in the future.

More recent studies have moved beyond looking at wall stress alone and have also focused on aortic wall strength. These two elements in combination provide a more accurate predictor of rupture, primarily due to the fact that as aortic size increases, wall stress increases with a concomitant decrease in wall strength.¹¹ Another element that remains poorly understood is the role of intraluminal thrombus. Models still need to be constructed that incorporate intraluminal thrombus to better understand its role in the rupture risk of AAA.

Hemodynamics

In addition to influencing rupture, hemodynamic factors may play an important role in aneurysm initiation and growth. Using the elastase infusion model in rats, research has established that increases in flow through the injured aorta decrease macrophage infiltration into the aortic media¹¹⁰ and increase macrophage antioxidative gene expression.¹¹¹ AAAs in these high-flow

groups also demonstrated a significant reduction in diameter compared with the low- and normal-flow groups. Expression of MMPs¹¹² and reactive oxygen species¹¹³ is also influenced by hemodynamic factors in experimental aneurysm formation.

CONCLUSION

Significant progress has been made over the past 20 years in delineating the pathogenesis of AAA. Both clinicians and basic scientists will continue to play important roles in studying this disease process. It is hoped that by enhancing our knowledge of the underlying pathology of AAA, new and improved methods of diagnosis and treatment will follow.

CHAPTER 98 ■ THORACIC AORTIC ANEURYSMS

GORAV AILAWADI

KEY POINTS

- 1 The risk of thoracic aneurysm disease increases with age. Thoracic aortic aneurysms in young patients are most likely due to genetic predisposition or familial syndromes.
- 2 Careful planning by experienced centers is paramount to provide optimal treatment in patients with thoracic aortic aneurysms as the morbidity and mortality for surgical intervention is significant.
- 3 Open surgical repair remains the mainstay for aortic root, ascending aortic, and aortic arch aneurysms with very acceptable outcomes and low morbidity when performed in centers with experienced staff.
- 4 Endovascular techniques for the descending thoracic aorta have become the preferred treatment approach not only for aneurysms but for dissections and traumatic aortic injuries as they often can be performed with less morbidity than that associated with open surgical treatment.
- 5 Endovascular repair still carries the risk of endoleak. In addition, spinal cord complications are similar with endovascular compared to open approaches.

Aortic diseases constitute the 13th leading cause of death in the developed world. Aneurysms can affect the ascending, arch, descending, or abdominal aorta. Aneurysms of the thoracic aorta, including the ascending, arch, and descending aorta, in particular, are associated with high morbidity and mortality (Fig. 98.1). An aortic aneurysm is defined as a dilation of the diameter of at least 50% greater than baseline. *True aortic aneurysms* affect all the layers of the aortic wall—intima, media, and adventitia—and should be distinguished from *false aneurysms*, which occur after trauma or other injury and consist of the media and adventitia. *Aortic dissections* are intimal tears resulting in blood propagating within the medial layer. *Intramural hematoma* is the presence of blood within the wall of the aorta without a definite intimal tear.

Although understanding of the pathogenesis of aortic aneurysms is rapidly evolving, degradation of the aortic extracellular matrix proteins, collagen and elastin, and loss of smooth muscle cells are hallmark pathologic findings. In contradistinction to abdominal aortic aneurysms, ascending aneurysms less

commonly display manifestations of atherosclerosis or an inflammatory infiltrate. Thoracic aortic disease is associated with high morbidity and mortality. Treatment decisions concerning operative intervention in terms of both timing and extent of resection are often complex and involve multidisciplinary management.

HISTORY

The first known description of an arterial aneurysm was by Galen, a Greek physician (A.D. 126–216), who described false aneurysms in injured gladiators.¹ It was not until 1895 that an etiology for aneurysms was hypothesized, when Dohle identified syphilitic aortitis.² Aneurysms were originally treated with external or internal ligation via opening the aneurysm. In the later 19th century, Rudolph Matas developed an alternate technique of obtaining proximal and distal control, aneurysm resection, and primary reconstruction. These techniques were successful in only a limited number of patients.

FIGURE 98.1. A: Sagittal CT scan showing an ascending aortic aneurysm. B: Computed tomography and angiogram of a patient with a fusiform descending thoracic aortic aneurysm.

The modern surgical treatment of aortic disease began in the 1950s, and the ensuing 20 to 30 years saw the development and failures of many novel techniques. In the early 1950s, the first resection of a descending thoracic aneurysm and replacement with homograft was reported.^{3,4} The first excision of a saccular ascending aortic aneurysm without cardiopulmonary bypass was performed by Michael DeBakey and Denton Cooley in Houston in 1952.⁵ In 1953, Dubost et al. in Paris and DeBakey and Cooley in Houston reported successful resection and reconstruction of the abdominal aorta with human aortic allograft.^{6,7} The same duo performed a repair of an acute traumatic aortic transection in 1954 through a left thoracotomy with the patient's core temperature reduced to 28°C using surface cooling. They subsequently reported the first successful resection of an ascending aneurysm with cardiopulmonary bypass in 1956 and the first successful arch aneurysm repair in 1957.^{8,9}

Dacron grafts, introduced by DeBakey,² largely replaced human allografts, avoiding the need for maintaining large tissue banks and allowing more facilities the ability to treat these patients. In addition, the development and refinement of the cardiopulmonary bypass machine, in large part by John Gibbon at Thomas Jefferson, revolutionized the open surgical repair of thoracic aortic disease. The importance of hypothermia for cerebral protection and specifically the use of hypothermic circulatory arrest was established by Randy Griepp et al. at Yale University.¹⁰ With these techniques in place, modern surgical practice to treat aortic disease was established.

PREVALENCE

The true incidence and prevalence of thoracic aortic aneurysms is likely underreported. In a Swedish autopsy study, the prevalence

TABLE 98.1**RISK FACTORS FOR THORACIC AORTIC ANEURYSMS**

Anatomic	Vascular disease
Annulo aortic ectasia	Uncontrolled hypertension
Aortic wall abnormalities	Inflammation
Bicuspid aortic valve	Aortic aneurysm
Chromosomal/genetic	Aortic arteritis
Marfan syndrome	Arthrosclerosis
Ehlers-Danlos syndrome (type IV)	Behçet disease
Noonan syndrome	Giant cell arteritis
Polycystic kidney disease	Ormond disease
Turner syndrome	Syphilis
Congenital	Takayasu arteritis
Aortic arch hypoplasia	Iatrogenic/idiopathic
Aortic coarctation	Aortic cannulation/cross-clamping
Congenital aortic stenosis	Endoluminal transcatheter therapy
Demographic	Graft anastomosis
Age (>60 years)	Instrumentation
Lifestyle	Sheehan syndrome
Cocaine	Valvular surgery
Dyslipidemia	
Pregnancy (preeclampsia)	
Smoking	

of thoracic aortic aneurysms was reported as 489 per 100,000 men and 437 per 100,000 women.¹¹ Stratified by age, 65-year-olds had approximately 400 asymptomatic thoracic aneurysms per 100,000 autopsies, whereas 80-year-olds had a prevalence of 670 per 100,000 autopsies.¹¹ The mean age at diagnosis is between 60 and 70 years. Men are diagnosed 10 years earlier on average and have a 2:1 to 3:1 predominance compared to women.¹² In a study of residents in Olmstead county, the prevalence of thoracic aneurysms was 5.9 cases per 100,000 people-years prior to 1980.¹³ This number increased to 10.4 cases per 100,000 people-years between 1980 and 1994.¹⁴

Interestingly, during the first half of the 20th century, thoracic aneurysms were far more common than abdominal aortic aneurysms because of the predominance of infectious aneurysm in the thoracic aorta. By 1964, however, less than half of aneurysms were in the thorax, primarily as a result of the decline in the incidence of syphilitic aortitis.¹⁵ Thoracic aneurysms compose 25% of all aortic aneurysms. Approximately 50% of thoracic aortic aneurysms involve the ascending aorta, 10% the aortic arch, and 45% the descending aorta.¹³ True thoracoabdominal aneurysms constitute less than 5% of thoracic aortic aneurysms.¹¹

ETIOLOGY AND RISK FACTORS

Although there has been a long-standing belief that aortic aneurysms represent a late degenerative stage of atherosclerosis,¹² this concept has been seriously challenged, and aneurysms are now viewed in terms of genetic and molecular mechanisms. Atherosclerotic disease is now thought to be associated with, rather than causative of, aneurysmal disease. Aneurysms associated with atherosclerosis of the aorta most commonly involve the descending or thoracoabdominal segments, whereas atherosclerosis is rarely associated with ascending aortic aneurysms.

Abnormal proteolysis, the presence of elastolytic serum enzymes and deficiencies of collagen and elastin have been implicated as factors contributing to the development of these

aneurysms.¹⁵ Atherosclerotic lesions of the thoracic aorta may ulcerate and penetrate the internal elastic lamina of the aortic wall, which can result in hemorrhage within the layers of the media leading to intramural hematoma, an entity on the continuum of aortic dissection. Once aneurysmal dilatation of the aorta has begun, it tends to progress. Whether this is due to a gradual but constant increase in size or episodic incremental increases is unknown. Associated chronic obstructive pulmonary disease, smoking, and hypertension are known to be risk factors and can increase the rate of aneurysm growth. Other disorders with genetic predisposition are also highly linked with thoracic aneurysms and include Marfan syndrome, Loeys-Dietz syndrome, Ehlers-Danlos syndrome, and Turner syndrome (Table 98.1).

Degenerative

The most common etiology for thoracic aortic aneurysm formation is cystic medial degeneration. Although the underlying mechanisms for this process are unknown, pathologic features include elastic fiber fragmentation, smooth muscle cell apoptosis, and local production of matrix-degrading enzymes, specifically matrix metalloproteinases (MMPs). The degree of atherosclerosis present in the aorta is dependent on the anatomy of the aneurysm. Ascending aortic aneurysms are degenerative often without extensive atherosclerosis, although atherosclerosis is often a feature associated with degenerative descending aneurysms. The pathogenesis of aortic aneurysms appears to be linked to a reduction in functional extracellular matrix proteins, elastin and collagen, either through enzymatic degradation or deficiencies in these structural proteins. Moreover, in some diseases with genetic predisposition, there is a shift in the expression of MMPs as well as the tissue inhibitors of MMPs (TIMPs) resulting in degradation of these proteins. For example, patients with bicuspid aortic valves are known to have altered expression of MMPs and TIMPs. As such, these patients have degenerative ascending aortic aneurysms often

FIGURE 98.2. A CT reconstruction demonstrating a chronic Stanford type A dissection (DeBakey type I) that has undergone late aneurysmal degeneration of the proximal descending thoracic aorta.

FIGURE 98.3. Reconstruction of a CT scan of an aortic root aneurysm in a patient with Marfan syndrome. Commonly the sinuses of Valsalva are involved with sparing of the aortic valve.

independent of any associated functional valve disease or atherosclerosis.

Chronic Aortic Dissection

A dissection occurs when blood enters the vessel wall through an intimal tear allowing propagation of blood between the medial and adventitial layers. Although ascending aortic aneurysms (Stanford A, or DeBakey types I and II) are treated emergently with open surgery, most descending thoracic aneurysms (Stanford B or DeBakey type III) do not rupture or result in malperfusion and are treated with medical management of hypertension and pain control. These aortas are prone to aneurysmal degeneration as the dissected aortic wall is inherently weak (Fig. 98.2). It is important to note that nearly all chronic ascending aortic dissections become aneurysmal, and roughly one third of descending thoracic aortic dissections become aneurysmal over time. Although the etiology is different with mechanical disruption of the medial and adventitial wall, the process of chronic aortic wall remodeling including production of MMPs may be similar.

Genetically Triggered

- 1 Although the risk of thoracic aortic aneurysm disease increases with age, thoracic aneurysms in young patients are most likely due to genetic predisposition or familial syndromes. Recently, several genetic etiologies linked to thoracic aneurysms have been elucidated. In particular, insights have been gained from a registry for the genetically triggered thoracic aortic aneurysms (TAA) and cardiovascular conditions (GenTAC) which has genetic information on more than 1,000 patients with thoracic aneurysms secondary to hereditary or genetic predisposition.¹⁶ The most common and notorious disease is Marfan syndrome, which is an autosomal dominant defect of the fibrillin gene located on chromosome 15. Mutation of fibrillin leads to instability of the elastic

fibers in the aortic media. The prevalence of aortic dilatation in Marfan syndrome is 70% to 80% and most commonly involves the aortic root and sinuses of Valsalva, rendering the aorta prone to rupture or dissection (Fig. 98.3). Marfan syndrome presents at an early age and tends to be more common in men than women. The cardinal features of the disorder include tall stature, ectopia lentis, mitral valve prolapse, aortic root dilatation, and aortic dissection. About three quarters of patients have an affected parent, while new mutations account for the remainder of cases.

Recently, mutations of transforming growth factor receptors I and II (TGFBR I, TGFBR II) termed Loeys-Dietz syndrome have been linked with thoracic aneurysms. These patients have a classic bifid uvula. Ehlers-Danlos syndrome encompasses a group of more than 10 disorders characterized by defects of collagen synthesis. The disease can range from hypermobility of the joints to extremely fragile skin and extreme muscle weakness. The common vascular Ehlers-Danlos (type 4) is caused by an autosomal dominant disorder of type III collagen. These patients are characterized by fragility of their blood vessels. Familial thoracic aortic aneurysms and dissections (FTAAD) is caused by mutations of the α actin II or myosin heavy chain (MYH11).¹⁷ Turner syndrome is defined by the loss of an X chromosome (XO). Patients with Turner are prone to aneurysmal degeneration of their ascending aorta.

Inflammatory

A host of rare inflammatory diseases of the aorta and great vessels including Takayasu arteritis, Behçet disease, Kawasaki disease, and giant cell arteritis can result in thoracic aortic aneurysms and can require surgical treatment. Detailed descriptions of these diseases are beyond the scope of this chapter.

Infections

In current practice, primary infections of the aorta are rare but do lead to aneurysms. Mycotic aneurysms can be caused by

bacterial, fungal, spirochetal, or viral agents. Prior to the antibiotic era, syphilis accounted for approximately 75% of all aneurysms. Mycotic aneurysms occur due to localized infections in the aortic or arterial walls, usually as the result of bacteremia. Infection of atherosclerotic plaques themselves can also result in mycotic aneurysms. As a result of trauma or due to infected lymph nodes, infection may also spread to blood vessel walls contiguously. Preexisting aortic aneurysms may also become infected, usually from bloodstream seeding. Although any pathogen may infect aneurysms, *Salmonella* species show a special proclivity for vascular tissues. Other organisms associated with mycotic aneurysms are *Staphylococcus* species, *Streptococcus* species, *Pasteurella multocida*, *Legionella anisa*, and *Escherichia coli*. Treatment consists of long-term antibiotics prior to and after surgical aneurysm resection.

Traumatic Pseudoaneurysm

Pseudoaneurysms are associated with trauma or previous operations on the aorta. Classically, rapid decelerating blunt trauma leads to aortic transection. In more than 50% of cases, the location of the aortic injury is just distal to the fixed ligamentum arteriosum, the remnant of the ductus arteriosus.^{18,19} For the 20% of patients who survive this acute event, the rupture is partially contained by the aortic adventitia and pleura. Of survivors, aneurysmal formation around the site of injury can occur and often dilates faster because it is an unsuspected injury, and utmost care with regard to their antihypertensive therapy has to be taken to avoid rupture. Given multisystem injuries often present in these high-speed injuries, many consider endovascular aortic repair the preferred approach for most of these patients.²⁰ Iatrogenic pseudoaneurysms occur following aortic surgery and can form at anastomotic sites or areas where an aortic cross-clamp was placed.

DIAGNOSIS

Most thoracic aneurysms are asymptomatic and are found incidentally. Symptomatic aneurysms are often diagnosed based on their anatomic sequelae. Patients with aneurysms of the ascending aorta may also present with fullness in the chest or signs and symptoms of aortic valve insufficiency. Acute chest pain may be caused by either expansion of the aneurysm or dissection of the aortic wall. Arch and descending thoracic aneurysms can present with hoarseness secondary to stretching of the left recurrent laryngeal nerve, stridor from tracheal compression, or dysphagia from esophageal compression.

There are multiple imaging modalities to diagnose thoracic aortic aneurysms. Plain chest radiograph can be suggestive whereas computed tomography (CT), magnetic resonance imaging (MRI), and transesophageal echocardiography (TEE) are definitive studies.²¹ CT is widely available and provides detailed information about the size, location, and extent of aortic disease as well as anatomic detail of surrounding mediastinal and thoracic structures. In particular, CT angiography is useful to plan endovascular approaches to repair. This is the most common means of evaluating and following the thoracic aorta although it requires exposure to radiation and nephrotoxic contrast material.

MRI offers detailed anatomy as CT does but does not require radiation. Gadolinium as a contrast agent has also recently been documented to be nephrotoxic. MRI requires lengthy image acquisition and processing times and is not as readily available as is CT. Moreover, MRI cannot be performed in patients with significant metallic implants such as pacemakers and defibrillators.

TEE avoids the use of these agents and offers good visualization of the ascending and descending thoracic aorta as well as cardiac structures. Because of the tracheal shadowing, imaging

of the aortic arch is limited. In addition, the technical expertise to perform and interpret TEE is not always readily available.

The once-preferred diagnostic test, catheter-based angiography, images only the lumen and does not provide information regarding the aortic wall.

MANAGEMENT AND NATURAL HISTORY

In three large thoracic aortic aneurysm studies, rupture was the most common cause of death (42%–70% of deaths) among those patients who did not undergo operation at the time of diagnosis.^{15,22,23} In all three series, the rate of rupture for aneurysms complicated by dissection substantially exceeded the rate for nondissected aneurysm.²⁴ Collectively, these studies indicate that an aggressive strategy to treat thoracic aneurysms is needed.

The management strategy is dictated by the aneurysm size and rate of growth. Aortic aneurysms that are large or that are rapidly enlarging are at risk of dissection or rupture. The risk of dissection or rupture increases in a nonlinear fashion as the size increases. Data from the Yale Center for Thoracic Aortic Disease, which has followed more than 3,000 patients with thoracic aortic aneurysms, has suggested that the risk of aortic complications in the ascending aorta increases significantly as the size approaches 6.0 cm, and in the descending thoracic aorta as the size approaches 7.0 cm.²⁵ Similarly, the Olmstead County registry (Minnesota) reported that a rupture rate of 16% at 3 years for 6-cm aneurysms compared to 31% for 7-cm aneurysms.¹⁴ The Yale group has reported the annual risk of death or aortic-related complication exceeds 15% in patients with aneurysms of 6.0 cm or greater compared to 5% in patients with aneurysms smaller than 5.0 cm. Other studies have supported this pattern, reporting a mean rate of rupture or dissection of 2% per year for small aneurysms, 3% for aneurysms 5.0 to 5.9 cm, and 6.9% for aneurysms 6.0 cm or greater in diameter.^{26,27} These data have formed the basis for size criteria to intervene prior to the attainment of the previously mentioned dimensions in an asymptomatic patient.

Recent studies have evaluated the risk of aortic complications based on aortic size individualized to body surface area (Table 98.2). In patients with a symptomatic aneurysm, however, surgical treatment should be performed irrespective of the size.

As for other aneurysms, the growth of thoracic aortic aneurysms is indolent. The typical rate of growth for ascending aortic aneurysms is 0.1 cm/year and for descending aneurysms is 0.3 cm/year.²⁵ The annual growth rates for patients suffering from chronic dissections are significantly higher, ranging from 0.24 cm/year for small aneurysms to 0.48 cm/year from large aneurysms.²⁶ Growth rates exceeding 5 to 7 mm/year for aneurysms or greater than 5 mm per 6 months for aortic dissections are considered harbingers of aortic complications, and earlier intervention should be considered.

MANAGEMENT

Since thoracic aneurysms increase in size until they rupture,^{12,26} the decision to intervene is critical. Preemptive surgical therapy should be applied at a size of 5.5 cm for ascending and arch aneurysms and 6.0 cm to 6.5 cm for descending aortic aneurysms in suitable surgical candidates to avoid aortic complications or death.^{26–28} These surgical threshold criteria should be modified for patients with Marfan syndrome or connective tissue disease in which preemptive surgery is appropriate at 4.5 cm for root and ascending aneurysms and 5.5 cm for descending aneurysms.²⁹ Some have further suggested that patients with Turner syndrome be treated surgically if the aortic diameter exceeds 4.0 cm due to the aggressive nature of aortic disease in these patients. Furthermore, any patient with

TABLE 98.2

RISK OF COMPLICATIONS BY AORTIC DIAMETER AND BODY SURFACE AREA (BSA) WITH AORTIC SIZE INDEX

■ BSA	■ AORTIC SIZE (cm)

Full-size table (<1K) = low risk (~4% per yr); Full-size table (<1K) = moderate risk (~8% per yr); Full-size table (<1K) = severe risk (~20% per yr). Reproduced with permission from Davies RR, Gallo A, Coady MA, et al., Novel measurement of relative aortic size predicts rupture of thoracic aortic aneurysms. *Ann Thorac Surg* 2006;81:169–177. Article | PDF (189 K) | View Record in Scopus | Cited By in Scopus (43)

symptoms or rapid growth as seen on sequential CT scans should have surgical intervention in a timely manner.

Once the need for intervention has been determined, a full cardiac evaluation should be completed including stress testing and angiographic evaluation of coronary arteries as indicated. The basic premise of open surgical repair for aneurysms, regardless of the situation, is replacement with an interposition graft with or without cardiopulmonary bypass. Intraoperative management is essential with central venous pressure and arterial monitoring as well as large-volume intravenous infusion lines. Intraoperative transesophageal echocardiography is useful to monitor fluid status and cardiac function during the operation.

Medical Management

Medical management by aggressive antihypertensive therapy can be used in asymptomatic patients with thoracic aneurysms in whom size criteria for surgical intervention has not been reached. While β -blockers and angiotensin-converting enzyme inhibitors/angiotensin receptor blockers are common treatments, studies are currently underway to indicate their efficacy in patients with aortic aneurysms. In mouse models of Marfan syndrome, ACE inhibitors prevented aneurysms.³⁰ Smoking cessation may be helpful in patients who have not developed chronic obstructive pulmonary disease (COPD). The diagnosis of COPD is a significant risk factor for aortic complications. It is unclear if risk factor modification of COPD once diagnosed can influence the likelihood of aortic rupture. Frequent imaging of these patients to assess changes in size should be performed to determine if surgery should be recommended.

Open Surgical Management of TAA

- 2 Careful planning by experienced medical personnel is paramount to providing optimal treatment in patients with thoracic aortic aneurysms as the morbidity and mortality for surgical intervention is significant. Over the years there have been substantial improvements in the intraoperative and postoperative management in patients with TAA. The approach and

techniques of repair vary widely based on the location of the thoracic aneurysm.

- 3 **Aortic Root and Ascending Aortic Aneurysms.** Open surgical repair remains the mainstay for aortic root, ascending aortic, and aortic arch aneurysms with very acceptable outcomes and low morbidity when performed in centers with experienced personnel. Operations to replace aortic root and ascending aorta are approached via a median sternotomy. All pathologic segments of the aorta are evaluated and replaced if abnormal, including the aortic valve, sinuses of Valsalva, the tubular portion of the ascending aorta, and the aortic arch. Cardiopulmonary bypass is established through right atrial (venous) cannulation and either aortic, femoral arterial cannulation or axillary artery cannulation. The heart is vented via the pulmonary artery or left atrium. The use of the axillary artery for cannulation allows for selective antegrade cerebral perfusion if circulatory arrest is needed during the replacement of the aorta³¹ (Fig. 98.4). The axillary artery is exposed via a 4-cm transverse incision 2 cm below and parallel to the clavicle. Once through the pectoral muscles, the axillary vein is isolated and retracted superiorly isolating the axillary artery. After systemic heparinization, an 8- or 10-mm Dacron graft is anastomosed in an end-to-side fashion onto the artery. The arterial cannula is then secured to the Dacron graft. Myocardial protection is achieved by infusion of antegrade blood cardioplegia into the coronary ostia and retrograde cardioplegia into the coronary sinus accompanied by a topical hypothermia.

If the aneurysm is contained to the root or ascending aorta and does not involve the aortic arch or head vessels, the heart can be arrested with the cross-clamp proximal to the innominate artery, and mild hypothermia can be used for systemic protection while the patient is maintained on cardiopulmonary bypass. A tube graft is then anastomosed distally then proximally using running monofilament suture. The aortic valve is also assessed with the aorta open and the valve repaired or replaced as necessary (Fig. 98.5). If the dilation of the aorta extends into the arch, deep hypothermic circulatory arrest (HCA) allows for complete resection and reconstruction of the diseased aorta and an open distal anastomosis in a bloodless field. Cerebral protection can be augmented by maintaining antegrade cerebral perfusion via the right axillary

FIGURE 98.4. Cannulation of the right axillary artery with direct arterial cannulation (A) or with the use of a side graft (B). Once established, axillary artery cannulation can allow for antegrade cerebral perfusion throughout the aortic replacement procedure. (Adapted from Sabik JF, Nemeh H, Lytle BW, et al. Cannulation of the axillary artery with a side graft reduces morbidity. *Ann Thorac Surg* 2004; 77:1315–1320.)

cannula and clamping the proximal innominate artery. The distal anastomosis is then performed in a timely manner. The cross-clamp is then reapplied to the graft, and full cardiopulmonary bypass can then resume. The proximal anastomosis is then completed encompassing all diseased portions of the ascending aorta and the aortic root.

Aneurysms involving the aortic root require isolation of the right and left coronary ostia and reimplantation into the Dacron tube graft. Care must be taken to ensure the coronary arteries are not kinked. In this setting the native aortic valve can be spared (valve-sparing root replacement) if the leaflets are normal or can be replaced with a valved conduit (Bentall procedure).

Aortic Arch Aneurysms. Operations involving replacement of the thoracic aortic arch are approached from a median sternotomy or bilateral anterior thoracotomies (clamshell incision) and use hypothermic circulatory arrest (HCA). HCA allows for a bloodless field while maintaining cerebral and visceral protection. In this setting, the patient is cooled to 16° to 20°C and the cardiopulmonary bypass circuit is turned off for up to 45 to 60 minutes. The use of selective antegrade cerebral perfusion (cannulation and perfusion of the right axillary artery with a

clamp on the proximal innominate artery) allows perfusion of the right carotid artery during operations of the aortic arch, maintains some perfusion to the brain, and reduces the risk of embolism and associated morbidity.³² Individual arterial cannulation of nondiseased arch vessels can be used as well to help ensure good cerebral perfusion. Replacement of the arch is often best performed with the use of a multibranched (trifurcated) aortic graft to allow individual anastomoses to each of the three great vessels (Fig. 98.6).^{32,33} This approach, rather than reimplanting an island of aortic tissue with all the great vessels, has been suggested to reduce the risk of embolization and minimizes the risk of late aneurysmal degeneration of the aortic patch.³³

Descending Aortic Aneurysms. Open surgical repair of the descending thoracic aneurysm is performed through a left posterolateral thoracotomy. Prior to positioning, a double-lumen endotracheal tube is placed for single-lung ventilation. In addition, a lumbar drain is often placed for cerebral spinal fluid (CSF) pressure monitoring and drainage to reduce the incidence of paraparesis and paraplegia caused by spinal cord ischemia, which can accompany resection of the aorta in the distal thoracic area.³⁴ The use of left heart bypass has been shown to decrease the risk of visceral and spinal cord ischemia. Pharmacologic agents, including barbiturates, naloxone, and steroids, may also help reduce neurologic injury when administered during the procedure. There are two options to perform this procedure: sequential clamping versus hypothermic circulatory arrest. If the arch is relatively spared and enough normal aorta can be identified distal to the left common carotid artery, a proximal clamp can be placed, which allows for left heart bypass. In using left heart bypass, the left atrium via the left inferior pulmonary vein and the femoral artery are cannulated. A centrifugal pump, heparin-bonded tubing, and minimal heparinization can be used, which can result in less bleeding than in traditional cardiopulmonary bypass. With this technique, moderate hypothermia is used with sequential aortic clamping, reimplantation of critical intercostal arteries, and the distal anastomosis constructed with peripheral perfusion via the femoral artery (Fig. 98.7).^{35–38} Conversely, for patients in whom the transverse arch cannot be safely clamped, profound hypothermic circulatory arrest is used for both cardiac protection and central and peripheral nervous system protection. With this technique, full cardiopulmonary bypass with cannulation of the femoral artery and femoral vein allows for cooling of the patient and deep hypothermic circulatory arrest and the proximal anastomoses can be performed in a bloodless field (Fig. 98.8). Other modalities used to help reduce paraparesis and paraplegia include monitoring of sensory evoked potentials and motor evoked potentials.³⁴ Epidural catheters are extremely beneficial for pain control and can improve early mobilization and pulmonary function. There is still great debate regarding the use of partial versus full cardiopulmonary bypass with these extensive aortic replacement surgeries.^{39,40}

After clamping the aorta (or initiating HCA), the aneurysm is opened and the proximal cuff is fashioned. An interposition graft is sutured to the proximal aorta in an end-to-end fashion. Once completed, cardiopulmonary bypass can be reinstituted and the graft clamped to perform the distal anastomoses when using HCA. The distal aorta and graft are then fashioned and an anastomosis created. Significant lumbar artery identified via preoperative computed tomographic aortography or intraoperative assessment can be reimplanted into the interposition graft. There is continued controversy regarding the necessity to perform this as this process can often take more than 30 minutes during which the aorta may be clamped. Once the affected portion of aorta has been successfully replaced, the patient can be appropriately warmed and hemostasis ensured. The patient is removed from cardiac support and thoracotomy closed in the usual manner. If the diaphragm was taken down, it should be reapproximated with interrupted nonabsorbable suture.

FIGURE 98.5. Operative repair of an ascending aortic aneurysm with distal clamping of the aorta. **A:** Valve replacement, when indicated, is performed after cardioplegic arrest. **B:** A full-thickness cuff of proximal aorta is developed and the aorta is transected just distal of the coronary ostia. **C:** The posterior suture line begins to the left of the left main coronary ostium and proceeds rightward, over the ostium. **D:** Completion of the distal suture line is performed prior to release of the cross-clamp. Careful measurement of the graft length ensures a tension-free distal anastomosis. (Adapted from Frist WH, Miller DC. Repair of ascending aortic aneurysms and dissections. *J Cardiac Surg* 1986;1:33–52.)

Endovascular Therapy

4 Open surgical procedures on the thoracic aorta, and particularly on the descending thoracic aorta, have significant mortality and morbidity. Endovascular techniques for the descending thoracic aorta have become the preferred treatment approach not only for aneurysms but for dissections and traumatic aortic injuries as they often can be performed with less morbidity

than that associated with open surgical treatment. Endovascular stent graft repair was first introduced by Parodi to treat the abdominal aorta.⁴¹ In 2005, the first commercially available device was approved by the FDA to treat descending thoracic aortic aneurysms. To date, there are three such approved devices—Gore (WL Gore Inc., Flagstaff, AZ); Medtronic (Medtronic, Minneapolis, MN); and Cook (Cook Medical, Bloomington, IN). Current grafts are as large as 45 mm and

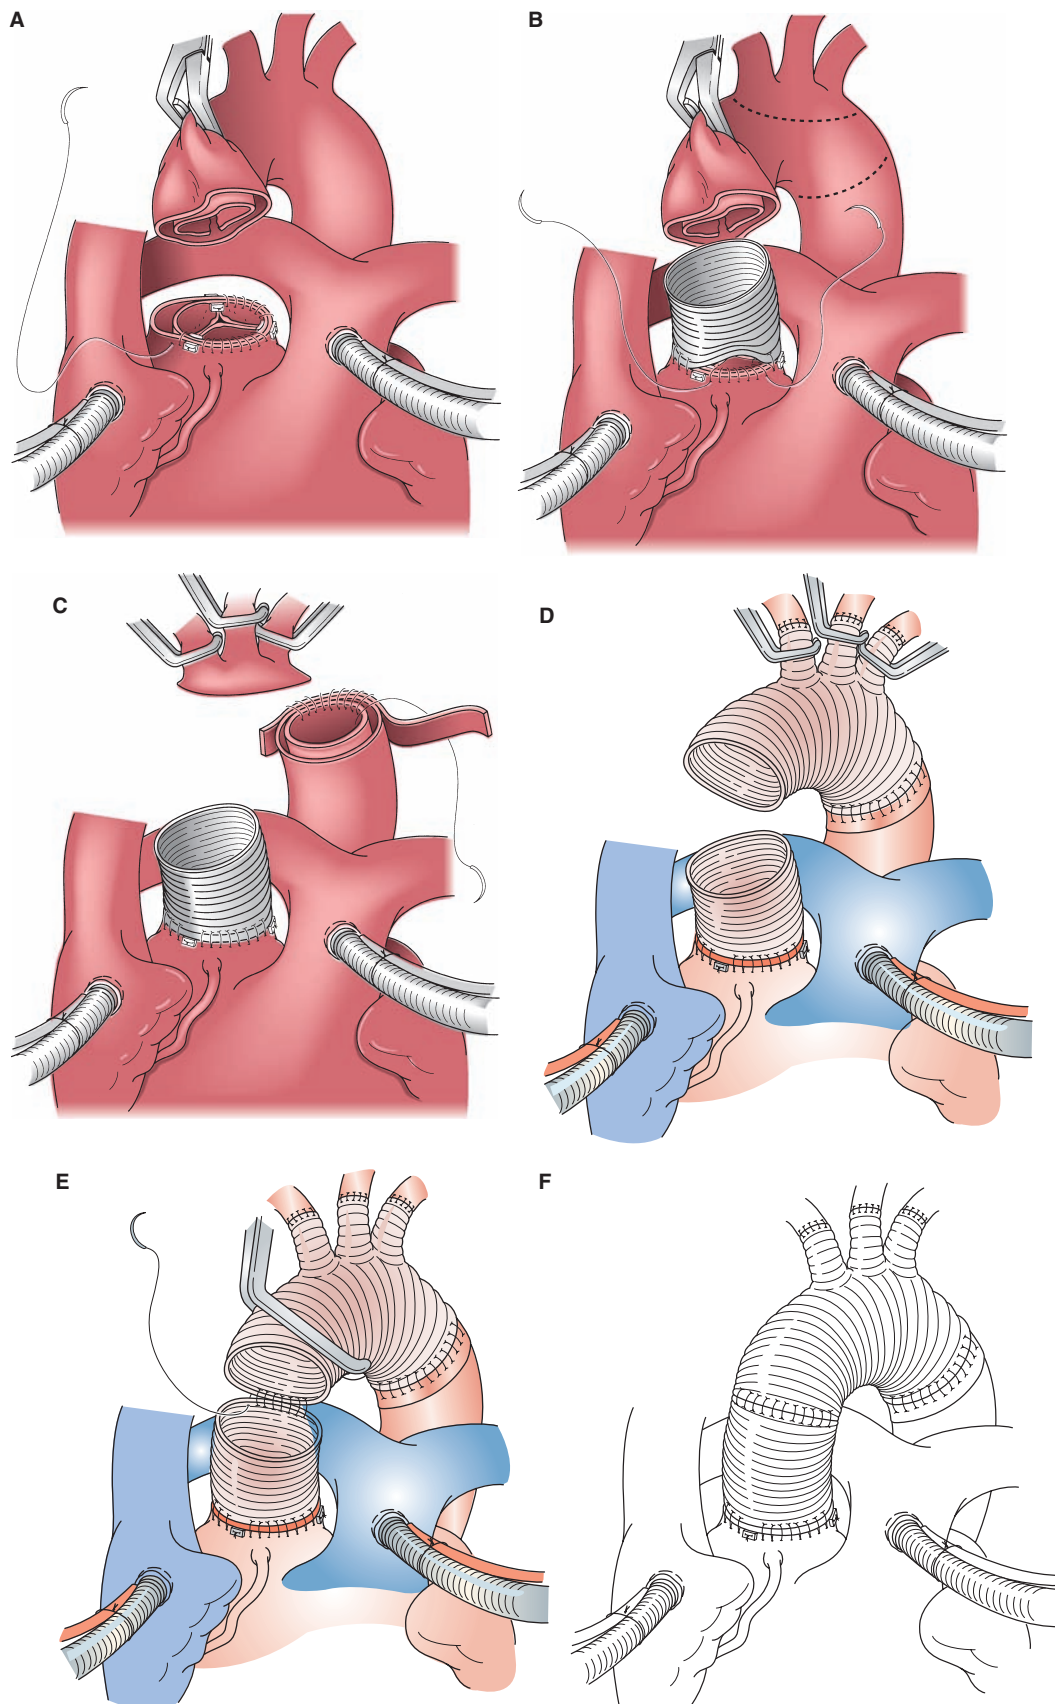

FIGURE 98.6. Repair of ascending and arch aneurysm with dissection. **A:** The ascending aorta is repaired first with the cross-clamp in place. **B:** While the ascending graft is placed proximally, the patient is cooled. **C:** During a period of hypothermic circulatory arrest (18°C), the distal aortic suture line is completed. **D:** The great vessels are reanastomosed separately using a trifurcated graft, or alternatively, an island of aorta containing the cerebral vessels can be fashioned. **E:** The cross-clamp is placed proximally, rewarming of the patient is instituted, and the proximal and distal grafts are joined. **F:** The repair as seen prior to decannulation. (Adapted from Griepp RB, Stinson EB, Hollingsworth JF, et al. Prosthetic replacement of the aortic arch. *J Thorac Cardiovasc Surg* 1975;70:1051–1063.)

FIGURE 98.7. Schematic of left heart bypass whereby partial bypass is used to maintain perfusion to the viscera and lower extremities. The inflow to the Bio-Medicus pump is the left inferior pulmonary vein, and the outflow is the left femoral artery. This technique avoids the need for an oxygenator.

thus can treat up to 40 to 42 mm diameter aorta. Grafts are made of polytetrafluoroethylene (PTFE) or woven polyester with steel or nitinol stents to maintain their shape. Preoperative CT with arterial phase contrast of the chest, abdomen, and pelvis is essential for operative planning. Critical elements to be gained from the CT include the following:

1. Aneurysm size and extent
2. Proximal and distal landing zones (a minimum of 2 cm of “normal” aorta is required)
3. Need for coverage of the left subclavian and assessment of preoperative carotid subclavian bypass (performed in setting of dominant left vertebral artery or patent left internal mammary artery bypass to the heart)
4. Angulation of the aortic arch and descending aorta
5. Size of femoral and iliac vessels and assessment of need for iliac conduit
6. Presence of thrombus along the aortic wall.

Stent grafts are oversized by approximately 10% to 15% from the CT cross-sectional diameter to obtain sufficient seal between the aorta and the graft. With this approach, the stent graft needs to be advanced into the thoracic aorta. This requires the size of the femoral and iliac arteries to be large enough to allow safe passage of the delivery sheaths. In general, 8-mm vessels are required to pass a 24-Fr sheath, which is the current sheath size for most of the available grafts. Once in place, an aortogram is performed to ensure proper positioning. A completion angiogram is performed to ensure no positioning, presence of kinks or endoleaks, or continued filling of the aneurysm sac. Finally, the decision is made regarding the need for additional stent grafts (Fig. 98.9).

The mortality with this approach has rapidly improved. In the first 100 patients treated at Stanford University (Stanford, CA), 60% of whom were nonoperative candidates, operative mortality was 10%.⁴² Homemade devices used in that study have evolved greatly. Recently, a study from the University of Virginia reported a 2% operative mortality in the first 50 patients in the FDA-approved era (2005–2006) where the treatment was

applied to a challenging group of patients.³⁰ Importantly, spinal cord ischemia occurred in 3%, stroke in 4%, and late endoleaks in 7%. Moreover, the 1-year survival was 92%.³⁰ Another recent study performed at the University of Pittsburgh demonstrated that the permanent paraplegia rate of 1.6% following endovascular repair was significantly better than that for open operation (5.1%, $p < 0.004$).⁴⁷ Multiple studies have supported these findings reporting lower mortality, early incidence of paraplegia, and renal failure following endovascular therapy versus open surgery for the descending thoracic aorta.^{43–45}

These encouraging short-term and midterm data have led to endovascular therapy becoming the preferred technique for treatment of descending thoracic aneurysms. It is important to note that long-term data are still limited regarding device failure and migration. In one of the few long-term studies, a report

from Brazil using a non-FDA-approved device in 255 patients over a 10-year period showed freedom from death at 3, 5, and 9 years of 96%, 89.1%, and 85.1%, respectively.⁵³ Stent grafts have been applied in other regions of the aorta. In particular, there are several reports of stent grafts placed in the ascending aorta in patients unable to undergo open operation (Fig. 98.10).

The most recent data from the Gore TAG multicenter trial show favorable implant characteristics, with decreased blood loss, intensive care unit stay, and total hospital stay compared to a nonrandomized cohort of open surgical patients.⁴⁶ Late follow-up to 2 years shows a low rate of migration (3%), low appearance of late endoleaks (9%) with most managed with new endografts, and a 17% incidence of increase in size of the aneurysm sac. There has been one open conversion, and no late ruptures, prompting the conclusion that for anatomically suitable patients,

FIGURE 98.10. Off-label stent graft repair of an ascending aortic pseudoaneurysm in an inoperable patient demonstrating good positioning of the stent graft and exclusion of the pseudoaneurysm.

stent graft repair produced similar long-term event-free survival and was associated with less perioperative morbidity.

Hybrid Procedures

As endovascular approaches have evolved, so too have the options for hybrid procedures combining open and endovascular surgery. Patients with combined arch and descending thoracic aneurysms are often ideal candidates for hybrid procedures. The traditional approach has been a two-stage open procedure (elephant trunk). In the first operation, the arch aneurysm is repaired under HCA via a median sternotomy. The distal end of the Dacron graft replacing the arch is sewn to the proximal descending aorta with a long cuff to allow for future repair of the descending aortic aneurysm in the second stage. In the second stage, the traditional procedure has been an open descending aneurysm repair using the long cuff left at the initial operation as the proximal new aorta. Stent graft therapy has allowed for the second stage to be performed less invasively with an endovascular approach. An alternative approach to these patients is revascularization of the arch vessels via sternotomy using a trifurcated graft off the ascending aorta to the great vessels. This can be performed without the use of cardiopulmonary bypass using a side-biting clamp on the ascending aorta. This is followed by endovascular repair of the arch and descending aorta covering the native take-off of the great vessels. Other patients who benefit from hybrid procedures include those with thoracoabdominal aneurysms who require debranching of visceral vessels prior to stent graft repair. The inflow for these debranching bypasses is traditionally from the iliac vessels but can include the proximal abdominal or descending thoracic aorta.

OUTCOMES AND COMPLICATIONS

Despite continued improvement in surgical technique and postoperative care, operative morbidity and mortality remain high for patients with thoracic aortic aneurysms. These

patients, in addition to aneurysmal disease, often have associated comorbidities including renal dysfunction, chronic obstructive lung disease, and ischemic heart disease. Preoperative assessment and management are paramount to facilitating good operative outcomes. Multiple studies have demonstrated the adverse effect on survival of emergent versus elective operation. Hospital mortality rates for emergency thoracic aneurysm repair can be as high as 30%, whereas elective mortality rates are less than 5%.⁴⁸ To predict risk after elective repair of ascending and aortic arch aneurysms, the Mount Sinai group analyzed multiple variables.⁴⁹ They found that the presence of diabetes and manifestations of atherosclerosis emerge as extremely important risk factors for adverse outcome after ascending and arch surgery, displacing age.

Ascending aorta replacement has relatively low mortality and morbidity. The need for circulatory arrest does increase the morbidity slightly with incrementally higher risks of stroke. Procedures on the aortic root, performed by experienced surgeons, carry mortality rates of less than 2%.⁵⁰

Studies focusing on descending thoracic aortic replacement outcomes have shown that the use of left heart bypass or complete cardiopulmonary bypass had favorable results compared with the “clamp-and-sew” techniques without cardiopulmonary bypass. Renal failure appears to be decreased with the use of bypass. However, the rates of paraplegia and paraparesis remain dependent on the extent of repair and clamp time.^{48,49} Nonetheless, use of combined adjuncts including CSF drainage, reimplantation of intercostal arteries, and distal aortic perfusion have reduced the overall early neurologic deficits rate from 7% to as low as 0.9%.^{49,51}

Endovascular therapy appears to have clear advantages with less operative mortality and morbidity, although it cannot be performed in all patients due to anatomic limitations. However, stent grafts still lead to a significant number of late complications to deal with postsurgery. The risk of spinal cord ischemia is not abrogated with endovascular therapy. Risk factors for spinal cord ischemia include coverage of the left subclavian artery, prior abdominal surgery, coverage of T8 to T12, and previous abdominal aortic surgery.

Moreover, endoleaks can occur late and need to be followed carefully. In our experience, early endoleaks occur in

FIGURE 98.11. A: A proximal type I endoleak in a different patient following endovascular repair of a type B dissection. B: CT reconstruction demonstrates proximal type I endoleak and distal filling of the false lumen via fenestrations below the stent graft.

more than 25% whereas 7% have late endoleaks necessitating repeat procedures (Fig. 98.11). The less common complications include component separation, migration, and endograft infection.⁵² Studies are still going on as to the comparative durability of the various types of endografts being used for the endovascular repair of the TAA.

CONCLUSIONS

Aneurysmal disease of the thoracic aorta has a high morbidity and mortality. Treatment of these patients requires careful preoperative planning, meticulous protection of the viscera and spinal cord, and rigorous follow-up. Endovascular therapy has become the preferred technique for descending thoracic aortic disease and offers patients less morbidity than that associated with open surgical treatment. Hybrid procedures allow the use of endovascular therapies beyond their usual anatomic limitations. The best outcomes for all patients who suffer from aneurysmal disease of the thoracic aorta are provided by a multidisciplinary approach with a firm understanding of the pathogenesis and natural history of this disease.

CHAPTER 99 ■ THORACOABDOMINAL AORTIC ANEURYSMS

HAZIM J. SAFI, ANTHONY L. ESTRERA, CHARLES C. MILLER III, ALI AZIZZADEH,
AND DIANNA MILEWICZ

KEY POINTS

- 1 Remarkable progress has been made in the surgical treatment of thoracoabdominal aortic aneurysms.
- 2 The decline in mortality and complication rates can be attributed to improvements in perioperative care and in surgical technique, particularly the adoption of adjunct distal aortic perfusion and cerebrospinal fluid drainage.
- 3 Neurologic deficit is no longer a major threat to patients, because the use of adjuncts has lowered the incidence for all thoracoabdominal aortic aneurysms to less than 2.5%.
- 4 Research needs to be continued that focuses on improving organ preservation, particularly for the most troublesome extent II thoracoabdominal aortic aneurysm.

Etheredge reported the first successful repair of a thoracoabdominal aortic aneurysm (TAAA) using a homograft tube in 1955.¹ A year later, DeBakey used a Dacron tube graft to replace the descending thoracic aorta and infrarenal abdominal aorta.² Subsequently, Crawford introduced what became known as the *clamp-and-go technique*, encompassing three basic principles of aortic surgery: the inclusion technique, use of a Dacron tube graft conduit, and reimplantation of visceral and renal arteries.³ Initially, the operation to repair TAAA had to be performed with haste, to avoid extended periods of

- 1 organ ischemia. TAAA surgery has since been transformed with the use of adjuncts that provide better organ protection and result in improved outcome; however, sudden fatal rupture of a TAAA remains a looming and unpredictable threat. Although emergency repair of ruptured TAAA can save lives, the associated morbidity and mortality remain extremely high. Elective surgical repair of TAAA is the only effective treatment for eradicating the risk of aneurysm rupture and improving patient survival (Fig. 99.1). This chapter provides a comprehensive approach to the diagnosis and management of TAAA, as well as insight into the recent surgical results and advances in organ protection.

EPIDEMIOLOGY

Abdominal aortic aneurysm remains a major cause of death in the United States. Improved imaging techniques, increasing mean age of the population, and overall heightened awareness all contribute to an apparent increase in the prevalence of aortic aneurysms. However, the incidence of TAAA from population studies of thoracic or abdominal aortic aneurysms can only be inferred. Infrarenal abdominal aortic aneurysms occur three to seven times more frequently than thoracic aortic aneurysms, as fewer than 1,000 TAAAs are repaired annually, compared with approximately 50,000 infrarenal abdominal aortic aneurysms. The estimated prevalence of abdominal aortic aneurysms varies between 2.3% and 10.7% depending on the population studied and the size used to define an aneurysm.⁴⁻⁶ The incidence of TAAAs is estimated to be 10.4 cases per 100,000 person-years.⁷ The mean age of patients with a TAAA is between 59 and 69 years, with a male-to-female predominance of between 2 and 4 to 1.⁸

Fewer than 40% of patients with untreated large TAAAs survive beyond 5 years, with most deaths caused by rupture.^{3,8-10} TAAA studies have shown that rupture is more likely to occur when aneurysms exceed 5 cm in diameter and that the rate of rupture rises with increasing aneurysm size.^{9,11-14} The median size at which TAAAs rupture is around 7 cm.^{15,16} Aneurysms equal to or greater than 8 cm have an 80% risk of rupture within 1 year of diagnosis.¹⁷ The lifetime probability of rupture for any untreated aortic aneurysm is 75% to 80%, but the size at which the aneurysm will rupture and how long it will take to reach that point cannot be easily calculated. However, the average overall rate of growth for TAAAs is 0.10 to 0.42 cm per year with an exponential growth rate for aneurysms exceeding 5 cm in diameter.^{11,16,18-20}

PATHOGENESIS

An aortic aneurysm is defined as a localized or diffuse dilatation that exceeds 50% of normal aortic diameter. Most TAAAs are degenerative, with an underlying pathology similar to the more frequently encountered infrarenal abdominal aortic aneurysm. Arteriosclerosis has long been implicated in the development of aortic aneurysm; however, arteriosclerosis primarily affects the intima and typically causes occlusive disease, whereas aneurysm disease usually involves the media and adventitia. Although the pathogenesis of arteriosclerotic occlusive disease and that of aneurysm disease have been shown to be distinct, the two conditions commonly occur together. Histologically, degenerative aortic aneurysms are characterized by thinning of the media with destruction of smooth muscle cells and elastin, infiltration of inflammatory cells, and neovascularization.²¹⁻²³ A chronic inflammatory infiltrate, composed of macrophages as well as T and B lymphocytes, is consistently observed in the outer layer of the aneurysm wall. The degree of vessel wall inflammation varies and the stimulus for cell migration remains unclear. These inflammatory cells, particularly macrophages, secrete proteases and elastases that can degrade the aortic wall; in turn, elastin degradation products may act as chemotactic agents for the influx of inflammatory cells.²¹ The role of matrix metalloproteinases (MMPs), the most prominent type of elastases, in the development of aortic aneurysms has emerged from both clinical and experimental studies. Increased elastases MMP-2, MMP-9, and MMP-12 have been found in aneurysmal aortic tissue.^{21,24-26}

FIGURE 99.1. Thoracoabdominal aortic aneurysm: comparison of survival rates in untreated patients versus surgically treated patients.

Many TAAAs result from chronic ascending and descending aortic dissections. Familial clustering of aortic dissections is evident because up to 20% of patients with ascending thoracic aortic aneurysms that predispose to aortic dissections have one or more first-degree relatives with the same affliction.^{27–29} Marfan syndrome, characterized by skeletal, ocular, and cardiovascular abnormalities, is the most common inherited connective tissue disorder related to aortic aneurysm and dissection. Marfan syndrome occurs at a frequency of 1 in 5,000 to 10,000 worldwide. Aortic dilatation observed in Marfan patients has been linked to mutations in fibrillin-1 protein, encoded by the *FBN1* gene. Other known genetic syndromes that predispose individuals to TAAA and dissection include Loeys-Dietz syndrome, Ehlers-Danlos syndrome, Turner syndrome, and polycystic kidney disease.^{30–33} In addition, families with multiple members who have thoracic aortic aneurysms and dissections have been reported in the literature.³⁴ In most of these families, the phenotype for TAAA and dissection is inherited in an autosomal dominant manner with marked variability in the age at onset of aortic disease and decreased penetrance.³⁴ Four genes have been identified for familial thoracic aortic aneurysms and dissections that account for 20% of this family condition. Mutations in the smooth muscle isoform of α -actin, encoded by *ACTA2*, are responsible for 15% of familial aortic disease. Other genes responsible for less than 2% include *MYH11*, *TGFBR2*, and *TGFBR1*.^{35–38}

A small percentage of TAAAs are the result of infection (mycotic aneurysms) or trauma (pseudoaneurysms). An infected aneurysm frequently results from bacterial or septic emboli that seed an atherosclerotic aorta. Another mechanism is contiguous spread from empyema or adjacent infected lymph nodes. Although any organism can infect the aortic wall, *Salmonella*, *Haemophilus influenza*, *Staphylococcus*, *Mycobacterium tuberculosis*, and *Treponema pallidum* spirochetes species are the most common.^{39,40} Infected aortic aneurysms are usually saccular and thought to be at greater risk for rupture. Chronic traumatic pseudoaneurysm of the aorta related to previously unrecognized traumatic transection is also prone to rupture, and surgical repair is warranted at the time of diagnosis.

Approximately 25% of TAAAs are associated with chronic aortic dissection. An estimated 20% to 40% of patients will develop aneurysms in the thoracoabdominal aorta within 2 to 5 years following acute aortic dissection.^{41–43} Persistent patency of the false aortic lumen is reported to be a significant

predictor of aneurysm formation.^{42,44} However, the presence of chronic aortic dissection or patent false lumen has not been linked to a higher risk of aortic rupture.⁴⁵ Aneurysmal disease occurs in more than one part of the aorta in approximately 20% of cases. The so-called “mega” aorta is an “extensive” aortic aneurysm involving the ascending, transverse arch, and entire thoracoabdominal aorta. Although associated factors include Marfan syndrome and chronic aortic dissection, the cause of extensive aortic aneurysm remains unknown.

CLINICAL MANIFESTATIONS

Aortic aneurysms can cause compressive symptoms, although most do not until they reach a large size. The most frequent complaint is ill-defined chronic back pain, although pain can also occur in the chest, flank or epigastrium. Acute changes in the characteristics and severity of pain can indicate sudden expansion or impending aortic rupture. Hoarseness, resulting from vocal cord paralysis caused by compression of the left recurrent laryngeal or vagus nerves, is frequently seen in patients with large aneurysms of the proximal descending thoracic aorta. Patients may also experience dyspnea related to compression of the tracheobronchial tree. A large aneurysm can exert pressure on the adjacent esophagus or duodenum, causing dysphagia or weight loss related to obstruction or early satiety. Direct erosion of the aneurysm into the adjacent tracheobronchial tree, esophagus, or both can cause exsanguination, presenting as massive hemoptysis or hematemesis, respectively. Less frequently, direct erosion can cause slow intermittent blood loss. Rarely, paraplegia or paraparesis can occur in patients with TAAA as a result of acute occlusion of the intercostal or spinal arteries. These findings are usually associated with acute aortic dissection, but can also result from thromboembolization. Although most aneurysms have a varying amount of mural thrombus, distal embolization causing acute mesenteric, renal, or lower extremity ischemia is infrequent.

Rupture is thought to be the first clinical manifestation of a TAAA in as many as 10% to 20% of patients. Figure 99.2 shows a CT scan of a ruptured TAAA. Note stranding in the retroperitoneum, denoting extravasation of blood. The acute onset of severe chest, abdominal, or back pain associated with

FIGURE 99.2. Computed tomography scan of a ruptured thoracoabdominal aortic aneurysm. Note stranding in the retroperitoneum denoting extravasation of blood.

FIGURE 99.3. Thoracoabdominal aortic aneurysm classification. Extent I, distal to the left subclavian artery to above the renal arteries. Extent II, distal to the left subclavian artery to below the renal arteries. Extent III, from the sixth intercostal space to below the renal arteries. Extent IV, from the 12th intercostal space to the iliac bifurcation (total abdominal aortic aneurysm). Extent V, below the sixth intercostal space to just above the renal arteries.

hypotension must raise the suspicion of a ruptured aneurysm. A pulsatile mass may be palpable in the abdomen; however, if the larger part of the TAAA is positioned deep within the thoracic cage, the aneurysm may not be apparent on physical examination. Although most ruptured aneurysms are fatal unless treated emergently, the ruptured arterial wall may temporarily seal for several hours or days before free rupture. In patients who are brought to the hospital alive, rupture is usually contained within the pleura or retroperitoneum. Free rupture is accompanied by severe hypotension and patients are more likely to die before reaching the hospital.

DIAGNOSTIC IMAGING

The diagnosis of TAAA can be confirmed by various imaging modalities. Currently, computed tomography angiography (CTA) is the imaging modality of choice in defining the extent of TAAA per the modified Crawford classification (Fig. 99.3) and for planning operative strategy. The diameter of the entire aorta, from the ascending segment to the bifurcation, can be accurately measured at various levels on axial images. The distinction between the false and true lumens in aortic dissection can be shown on CTA images. CTA can also detect thrombus or inflammatory changes in the aortic wall. Furthermore, the presence of free (or contained) fluid or blood can indicate free (or contained) rupture. Thin-slice CTA image acquisition can also identify patent intercostal arteries. Coronal reformatting or three-dimensional reconstruction of axial CT images provides additional views of TAAA (Fig. 99.4). Intravenous iodinated contrast can be omitted in patients with impaired renal function because it is not required for simple sizing of TAAA.

Magnetic resonance angiography (MRA) has become widely available and is frequently used as a screening test to detect diseases of the aorta and its branches. The principal advantage of MRA over CTA is that MRA does not require intravenous iodinated contrast and thus can be performed safely in patients with impaired renal function. In addition, MRA avoids the radiation exposure required for CT, especially when serial follow-up examinations are required. Although

FIGURE 99.4. Sagittal computed tomography image of an extent II thoracoabdominal aortic aneurysm.

MRA provides better contrast resolution, its spatial resolution is poorer than that of spiral CT. In addition, CT can better demonstrate aortic calcification and intramural thrombus compared with MRA. The time required to acquire images, claustrophobia, internal metallic hardware (e.g., pacemakers, orthopedic rods), and higher cost are other limiting factors of MRA.

Transesophageal echocardiography (TEE) can provide excellent imaging of the ascending and descending thoracic aorta. TEE can be performed at the bedside or in the operating room. TEE can be used in patients who are too unstable to be transported to the CT scanner. TEE can show aortic wall disease, differentiating arteriosclerotic plaque from intimal tear due to dissection. In the operating room, TEE can also be used to locate the optimal area for aortic cross-clamping and to assess cardiac function. However, TEE is an invasive modality and requires an experienced operator for optimal visualization and interpretation. Examination of the aorta by TEE is limited to the supradiaphragmatic aorta because the ultrasound probe loses contact with the aorta as it crosses the gastroesophageal junction.

PREOPERATIVE EVALUATION

The initial consultation with the TAAA patient focuses on a thorough history and physical examination, primarily to detect comorbidities because there are generally few symptoms or physical signs related to the aneurysm itself. The extent of the TAAA is determined from imaging studies. Further evaluation of associated risk factors is performed, and consultation with a cardiologist, pulmonologist, or nephrologist is often necessary to aid in the stratification of risks.

Ischemic heart disease is prevalent in this population and is the most common cause of death in patients with a TAAA. TEE provides an excellent estimate of cardiac function. Coronary artery revascularization for critically stenosed coronary artery disease, using either percutaneous intervention (balloon angioplasty or stent) or surgical bypass, may be indicated prior to TAAA surgery, but the risk of rupture of the aneurysm must be weighed against the risk of coronary intervention and the delay caused by intervention. For patients who must undergo coronary artery bypass prior to TAAA repair, the conduit of choice is the saphenous vein graft. The left internal mammary artery is avoided to obviate the possibility of cardiac ischemia should aortic cross-clamping proximal to the left subclavian artery be required during the TAAA repair. Moreover, the internal mammary artery may be an important collateral blood supply to the spinal cord and chest wall.

OPERATIVE TECHNIQUES

The patient is brought to the operating room and placed in the supine position on the operating table and prepared for surgery. The right radial artery is cannulated for continuous arterial pressure monitoring. General anesthesia is induced. Endotracheal intubation is established using a double-lumen tube for selective one-lung ventilation during surgery. A sheath is inserted in the internal jugular vein, and a pulmonary balloon-tipped catheter is floated into the pulmonary artery for continuous monitoring of the central venous and pulmonary artery pressures. Large-bore central and peripheral venous lines are established for fluid and blood replacement therapy. Temperature probes are placed in the patient's nasopharynx, rectum, or bladder. Electrodes are attached to the scalp for electroencephalography and along the spinal cord for both motor and somatosensory evoked potential to assess the central nervous system and spinal cord function, respectively (Fig. 99.5). The patient is then positioned on the right side with the hips and knees flexed to open the intervertebral spaces. A lumbar catheter is placed in the third or fourth lumbar space to provide cerebrospinal fluid (CSF) pressure monitoring and drainage (Fig. 99.6). The CSF pressure is kept at 10 mm Hg or less by gravity drainage of CSF fluid throughout the procedure. The patient is then repositioned in the right lateral decubitus position with the hips slightly turned to allow access to both groins. The operative field is scrubbed using standard aseptic solution and draped.

The incision is tailored to complement the extent of the aneurysm (Fig. 99.7). The full thoracoabdominal incision begins posteriorly between the tip of the scapula and the spinous process, curving along the sixth intercostal space to the costal cartilage, then obliquely to the umbilicus, and finally in the midline to above the symphysis pubis. The latissimus dorsi muscle is divided and the insertion of the serratus anterior muscle is mobilized. The left lung is deflated and the left thoracic cavity is entered. Resection of the sixth rib facilitates exposure and is routinely performed for all TAAAs, except extent IV. Usually, a full thoracoabdominal exploration is necessary for extent II, III, and IV TAAAs. A modified thoracoabdominal incision begins similar to the full thoracoabdominal incision, but ends at the costal cartilage or above the umbilicus. The modified thoracoabdominal incision provides excellent exposure for surgery involving the descending thoracic aorta, extent I TAAA, and extent V TAAA when the aneurysm ends above the superior mesenteric artery. The thoracoabdominal incision is extended to the level of the umbilicus for extent I and V TAAAs that involve the superior mesenteric artery. A self-retaining retractor is

FIGURE 99.5. Somatosensory and motor evoked potentials are recorded at three sites: the popliteal fossa (A, B), C5 (C), and the vertex (D).

FIGURE 99.6. Placement of the lumbar catheter in the third or fourth lumbar space to provide cerebrospinal fluid drainage and pressure monitoring.

placed firmly on the edges of the incision to maintain full thoracic and abdominal exposure during the procedure.

The dissection begins at the level of the hilum of the lung cephalad to the proximal descending thoracic aorta. The ligamentum arteriosum is identified and transected, taking care to avoid injury to the left recurrent laryngeal nerve. The extent of the distal abdominal aneurysm is assessed. Only the muscular portion of the diaphragm is divided and the left phrenic nerve preserved (Fig. 99.8A, B). A retroperitoneal plane is then developed, mobilizing the spleen, bowel loops, and left kidney to the right side of the abdominal aorta (medial visceral rotation). To prepare for distal aortic perfusion, the patient is anticoagulated using intravenous heparin (1 mg/kg body weight). The pericardium is opened posterior to the left phrenic nerve to allow direct visualization of the pulmonary veins and left atrium. The left atrium is cannulated through the left inferior pulmonary vein or atrial appendage. A centrifugal pump with an in-line heat exchanger is attached to the left atrial cannula and the arterial inflow is established through the left common femoral artery, or the descending thoracic aorta, if the femoral artery is not accessible. Distal aortic perfusion is begun (Fig. 99.9).

Padded clamps are applied onto the proximal descending thoracic aorta just distal to the left subclavian artery and the midthoracic aorta. When the proximal extent of the aneurysm is too close to the left subclavian artery, the aorta between the left common and left subclavian arteries is clamped. The left subclavian artery is clamped separately. Because of the danger

of graft-esophageal fistula, the inclusion technique for the proximal anastomosis is no longer used. Instead, the aorta is transected to separate it from the underlying esophagus (Fig. 99.10A). A woven Dacron graft impregnated with collagen or gelatin for replacement is preferred. The graft is sutured in an end-to-end fashion to the descending thoracic aorta, using a running 3-0 or 2-0 monofilament polypropylene suture. The anastomosis is checked for bleeding. Pledgeted polypropylene sutures for reinforcement are placed, if necessary. Sequential clamping is used for all TAAAs. After completion of the proximal anastomosis, the middescending aortic clamp is moved distally onto the abdominal aorta at the celiac axis to accommodate intercostal reattachment. Reattachment of patent, lower intercostal arteries (T8 to T12) is performed routinely, except in cases of occluded arteries, heavily calcified aorta, or acute aortic dissection. After completion of intercostal reattachment, the proximal clamp is released from the aorta and reapplied on the aortic graft beyond the intercostal patch, restoring pulsatile flow to the reattached intercostal arteries (Fig. 99.10B). The distal clamp is moved onto the infrarenal aorta, the abdominal aorta is opened, and the graft is passed through the aortic hiatus. The celiac, superior mesenteric, and renal arteries are identified and perfused using 9- or 12-French balloon-tipped catheters, depending on the size of the ostia (Fig. 99.10C). The delivery of cold perfusate (4°C) to the viscera depends on the proximal aortic pressure, which is maintained between 300 and 600 mL/min. Renal temperature is directly monitored and

FIGURE 99.7. Tailoring of thoracoabdominal incisions for aneurysm extent. DTAA, descending thoracic aortic aneurysm; SMA, superior mesenteric artery; TAAA, thoracoabdominal aortic aneurysm.

FIGURE 99.8. In previous surgical practice, the diaphragm was divided (A); currently, only the muscular portion of the diaphragm is cut (B).

FIGURE 99.9. Distal aortic perfusion from the left inferior pulmonary vein to the left common femoral artery.

kept at approximately 15°C. The visceral vessels are usually reattached using the inclusion technique. On completion of this anastomosis, the proximal clamp is moved beyond the visceral patch, restoring pulsatile flow to the viscera and kidneys (Fig. 99.10D). The final graft anastomosis is then completed at the aortic bifurcation. In most cases an island patch accommodates reattachment of the celiac, superior mesenteric, and both renal arteries. If the right or left renal artery is located at too great a distance from other arteries, its reattachment usually requires a separate interposition bypass graft. A visceral patch is no longer used for Marfan patients because of the high incidence of recurrent patch aneurysms in such cases. Instead, a woven Dacron commercially available graft is used with side-arm grafts of 10 mm and 12 mm for separate attachment of the celiac, superior mesenteric, and the left and right renal arteries.

The patient is weaned from partial bypass once the core body or nasopharyngeal temperature reaches 36°C. Protamine is administered (1 mg/1 mg heparin), and the atrial and femoral cannulae are removed. Once hemostasis is achieved, two or sometimes three 36-French chest tubes are placed in the pleural cavity for drainage. The diaphragm is reapproximated using running 1-0 polypropylene suture. The left lung is reinflated. Closure of the incision is done in a standard fashion. The patient is placed in the supine position, and a single-lumen endotracheal tube is exchanged for the double-lumen tube. If the vocal cords are swollen, the double-lumen tube is kept in

FIGURE 99.10. Sequential clamping and graft replacement. Padded clamps are placed on the proximal and middistal descending thoracic aorta. **A:** The proximal part of the aneurysm is opened. The aortic neck is completely transected and separated from the esophagus. The proximal anastomosis is fashioned. Subsequently, the patent lower intercostal arteries are reattached via an elliptical hole in the graft. **B:** The proximal clamp is then moved onto the graft to restore pulsatile flow to the intercostal arteries, and the graft is pulled through the hiatus into the abdomen. The distal clamp is reapplied onto the infrarenal aorta. The remainder of the aneurysm is opened. Balloon-tipped catheters are inserted into the celiac, superior mesenteric, and renal arteries to permit perfusion. **C:** An elliptical hole is made in the graft for reimplantation of the visceral and renal arteries.

place until the swelling resolves. The patient is then transferred to the intensive care unit (ICU). Figure 99.11 shows an extent II TAAA before and after surgery.

Elephant Trunk Technique for Extensive Aortic Aneurysms

Single-stage repair of extensive aneurysms involving the ascending, arch, and thoracoabdominal aorta greatly increases operative risks. The patient undergoes a lengthy procedure that requires multiple incisions, a daunting array of protective surgical adjuncts, protracted clamp times, and considerable blood loss. Staged repair is a practical solution. Prior to the introduction of the elephant trunk technique by Borst⁴⁶ in 1983, staged repair was fraught with complications, particularly excessive bleeding from the pulmonary artery and thoracic aorta in the second-stage repair of the thoracic or thoracoabdominal aorta. The elephant trunk technique resolves this problem because it allows the surgeon to avoid surgical manipulation and cross-clamping the proximal native descending thoracic aorta in the second stage.

The first stage of the elephant trunk technique is performed, in a similar fashion to standard surgery of the ascending aorta and transverse arch, with the exception that either an inverted distal graft or a commercially available collared graft is inserted distally (Fig. 99.12A). The folded edge of the inverted graft or the collared portion of the elephant trunk graft is sutured to the descending thoracic aorta just distal to the left subclavian

artery. When the distal anastomosis is completed, the inner portion of the inverted graft is retrieved. A side hole is made in the graft, and the aortic island containing the great vessels is reimplanted. The proximal anastomosis to the ascending aorta is completed, and the distal portion of the graft, or “elephant trunk,” is left dangling in the proximal descending aorta. In the first stage, cardiopulmonary bypass, profound hypothermia, circulatory arrest, and retrograde cerebral perfusion provide protection to the brain and guard against stroke.

The second stage of the elephant trunk technique is much like standard TAAA repair, using the adjuncts distal aortic perfusion and CSF drainage. After initiation of the pump, the distal clamp is applied at the middescending thoracic aorta. The proximal third of the descending thoracic aorta is opened without a proximal clamp. The elephant trunk portion of the graft, inserted in the descending thoracic aorta during stage 1, is grasped quickly and clamped (Fig. 99.12B, C). The new graft is sutured to the “elephant trunk” to replace the remaining aneurysm.

POSTOPERATIVE MANAGEMENT

In the ICU, the patient’s hemodynamic status is monitored very closely. The patient is awakened as quickly as possible to check neurologic status. However, most patients are kept on mechanical ventilation the first postoperative night. Blood loss is liberally replaced using banked blood products. The patient’s mean arterial pressure is maintained between 80 and 90 mm Hg to ensure adequate organ perfusion, particularly to the spinal cord. CSF

FIGURE 99.11. Example of thoracoabdominal aortic aneurysm extent II repair. **A:** Preoperative computed tomography showing proximal part of the aneurysm with chronic dissection. Intraoperative photograph of the thoracoabdominal aortic aneurysm before (B) and after (C) graft replacement. The proximal anastomosis was just distal to the left subclavian artery; the patent lower intercostal arteries were reattached; the celiac, superior mesenteric, and right renal arteries were reimplanted together; the left renal artery was reimplanted via an interposition bypass graft; and the distal anastomosis was to the aorta just above the bifurcation. The separate left renal artery graft was necessary because it was located far away from the remaining visceral arteries.

A

B

C

FIGURE 99.12. Elephant trunk technique. Illustration of completed stage 1 elephant trunk (A). In stage 2, the proximal aneurysm is opened and the existing graft is quickly grasped (B) and clamped (C). The remainder of the surgery follows the standard technique for thoracoabdominal aortic aneurysm.

pressure is continuously monitored. Approximately 10 to 15 mL of CSF is drained hourly to keep CSF pressure at 10 mm Hg or less. Ideally, the patient is weaned off the ventilator on the first postoperative day. Oral diet is resumed when the patient is extubated and has bowel sounds. If the patient requires longer mechanical ventilation, then a nasoduodenal feeding tube is placed and enteral feeding begins on the second or third postoperative day, when bowel activity returns. Some patients may develop postoperative ileus and require total parenteral nutrition. After the patient recovers from anesthesia and is moving all extremities, potential delayed neurologic deficit is monitored. Warning signs for delayed neurologic deficit are unstable arterial blood pressure, hypoxemia, low hemoglobin (<10 g/dL), or increased CSF pressure (>15 mm Hg). CSF drainage is discontinued on the third postoperative day. The length of stay in the ICU is about 3 or 4 days, depending on the neurologic and pulmonary status of the patient. The patient is subsequently transferred to the telemetry floor. Physical therapy is initiated in the ICU and continued throughout the patient's hospital stay. The median length of stay for patients following TAAA is 15 days.⁴⁷ Annual CT scan follow-up is recommended to screen for the development of new aneurysm or graft-related pseudoaneurysm formation. The frequency of follow-up visits or CT scans varies based on TAAA etiology. For example, patients with remaining unoperated aortic dissection, connective tissue disorders (Marfan syndrome), a family history of aortic aneurysm, or concurrent aneurysms may need closer surveillance.

SURGICAL OUTCOMES

Mortality rates for patients undergoing TAAA and descending thoracic aortic aneurysm repair range between 4% and 21%.^{12,48–50} The variable success rates are partly related to the heterogeneity of the patient population and to the expertise of the treating team. In the cumulative experience of the authors of this chapter (from January 1991 to July 2007), 1,353 patients underwent TAAA and descending thoracic aortic aneurysm repair.⁵¹ Of these patients, 63% were men with a median age of 65 years (range, 8 to 89 years). Approximately 7% of patients had emergency surgery for free or contained rupture of TAAA or descending thoracic aortic aneurysm. Currently, the 30-day mortality rate is approximately 14%, but for patients with normal renal function (i.e., with a calculated glomerular filtration rate >90 mL/min/1.73 m²), the early mortality was 5%. Using multivariable analysis, advanced age, renal failure, and paraplegia have been identified as important risk factors for mortality.⁵² Overall, 70% of patients recover from TAAA without significant postoperative complications.⁵³ The 5-year survival for patients after TAAA is between 60% and 70%. Recently, negative predictors for long-term survival were found to include advanced age, extent II TAAA, renal failure, emergency surgery, cerebrovascular disease, and active tobacco smoking.⁵²

Neurologic Outcome

Postoperative neurologic deficit remains the most devastating complication following TAAA repair. When the descending thoracic aorta is cross-clamped, the spinal cord is quickly rendered ischemic because of the immediate interruption of perfusion to the spinal cord and consequent increased CSF pressure. Therefore, in the “cross-clamp-and-go” era the single most important predictor of neurologic deficit was the length of clamp time. The rationale for the present method of protection is to increase the spinal cord perfusion pressure directly with distal aortic perfusion and indirectly by reducing CSF pressure to 10 mm Hg or less. Animal and human studies have confirmed that CSF drainage reduces CSF pressure and can improve spinal cord perfusion during aortic cross-clamping.^{54–56}

From January 1991 to July 2007, we performed repair of the descending thoracic and thoracoabdominal aorta in 1,353

FIGURE 99.13. In extent II aneurysms, the probability of developing neurologic deficits increases with increasing clamp time, but the use of adjunct distal aortic perfusion and cerebrospinal fluid drainage reduces the chances of neurologic deficit by prolonging ischemic tolerance.

patients.⁵¹ Nine hundred sixty-nine (71%) were male. The adjuncts distal aortic perfusion and CSF drainage with moderate hypothermia were used in 1,025 of 1,353 (76%) patients.

2 In our cumulative experience, the use of combined adjunct distal aortic perfusion and CSF drainage has been associated with a 58% reduction in the risk of neurologic deficit across all aneurysm extents. That is, the overall incidence of neurologic deficit for all patients without the use of adjunct was 5.2%, while it was 2.2% for those with adjunct. While aortic cross-clamp time remains a major predictor of paraplegia when plotted on a continuum, the curve has shifted to the right, with longer ischemic tolerance provided by the adjuncts. In high-risk extent II aneurysms, adjuncts reduced neurologic deficit from 30% to 9% at the average aortic cross-clamp time of 75 minutes (Fig. 99.13). When all aneurysm extents are modeled together with nonadjunct cases excluded, use of adjuncts has pushed the rates down to the range of 1% to 5% and vastly increased clamp time tolerance. This combination of results has made the current statistical models insensitive to cross-clamp time, so that although the intercept for extent II aneurysms is greater, the estimates for all extents are flat across clamp time (Fig. 99.14). Clearly, the adoption of adjunct has impacted the overall incidence of neurologic deficit, and this has led us to recategorize “low” versus “high” risk as “extent non-II” versus “extent II.”⁵⁷

Since 1991, distal aortic perfusion and CSF drainage have been utilized as adjuncts for all patients undergoing elective repair of TAAA. Overall, in a total of 1,004 patients, immediate postoperative neurologic deficit (paraplegia or paraparesis that occurs as the patient awakens from anesthesia) occurred in 2.4% of patients operated with adjuncts and in 6.8% of patients without adjuncts.⁵² This combination of adjuncts has reduced the cumulative rate of neurologic deficits to 0.9% for descending thoracic aortic repair and to 3.3% for thoracoabdominal aortic repair.⁵² Repair of the most extensive TAAAs (extent II) has long been known to result in the highest incidence of neurologic deficits. In the cross-clamp-and-go era, this incidence was as high as 30% to 40%.⁵⁰ With the use of adjuncts, the rate of immediate neurologic deficits for extent II TAAA has been reduced to 6.6%⁵² (Fig. 99.15). In addition to the extent of the aneurysm, other perioperative risk factors for immediate neurologic deficits include age, emergency presentation, renal dysfunction, active smoking, and cerebrovascular

FIGURE 99.14. For thoracoabdominal aortic aneurysms and all other aneurysms, use of adjuncts has made the probability of neurologic deficits low and unrelated to cross-clamp time.

disease. The use of intraoperative distal aortic perfusion and perioperative CSF drainage, in combination, prevents one neurologic deficit in 20 cases for all patients, and one in five for extent II TAAA.⁵²

Also important in spinal cord protection is the reimplantation of intercostal arteries. During the era of cross-clamp and go, reimplantation of intercostal arteries was found to be a risk factor for postoperative neurologic deficit.⁵⁸ This link was explained by the longer cross-clamp time required to reattach the intercostal arteries. The level at which the anterior radicular artery, known as the *artery of Adamkiewicz* or *arteria radicularis magna*, originates is known to be variable. Most commonly this artery branches from one of the lower intercostal arteries with or without additional collateral branches from nearby intercostal arteries. The anterior radicular artery is believed to be the major blood supply to the anterior spinal artery of the spinal cord. The relationship of neurologic deficit to ligation, reimplantation, and preexisting occlusion of inter-

costal arteries in patients undergoing TAAA repair using adjuncts has been studied. It was found that ligation of patent lower intercostal arteries (T9 to T12) increased the risk of paraplegia.⁵⁸ Therefore, all patent lower intercostal arteries from T9 to T12 are reattached, either together as a patch to a side hole made in the Dacron graft or, when the intercostal arteries are too far apart, separately as buttons or using interposition bypass grafts. However, if the lower intercostal arteries are occluded, the patent upper intercostal arteries will be reimplanted, because these are thought to assume a more important role in the collateral system to the anterior spinal artery in this situation.

Adequate spinal cord perfusion pressure should be maintained with avoidance of hypotension during and after surgery. Intravenous nitroprusside, in particular, can precipitate systemic hypotension, and has been shown to cause a paradoxical increase of CSF pressure.⁵⁹ Therefore, it is no longer used. A detailed account of the essential anesthetic care during TAAA repair is beyond the scope of this chapter. However, the importance of adequate maintenance of systemic arterial pressure with judicious blood transfusion cannot be overemphasized, as organ perfusion greatly depends on the systemic circulation. Clearly, the era of cross-clamp and go is over, and the spinal cord must be provided with some form of protection.

Cord function can be assessed using intraoperative neurophysiologic monitoring with motor evoked potentials (MEPs) and somatosensory evoked potentials (SSEPs) as performed routinely in aortic surgery.^{60,61} For SSEPs, probes are placed at the malleolus bilaterally, stimulating the posterior tibial nerve. Recordings are performed at three sites (Fig. 99.5), including the popliteal fossa, C5, and the vertex, with a positive finding defined as a drop in amplitude by 50% and/or a change in latency by 10%. For MEPs, precentral gyrus is stimulated and recording is measured at three sites including the abductor digit minimi, tibialis anterior, and abductor hallucis muscle. Compound muscle action potential is monitored, with a positive finding defined as an all-or-none potential. If there are signal changes as defined earlier, intraoperative corrective measures are performed, which include increasing the mean central pressure to over 80 mm Hg, increasing distal aortic perfusion pressure to over 60 mm Hg, lowering the CSF pressure, increasing the hemoglobin level, and attaching additional intercostal arteries.

With the current use of adjunct therapy and intraoperative SSEP and MEP monitoring, the current rate of immediate neurologic deficit remains at 3.1%.⁶²

Delayed Neurologic Deficits. Delayed neurologic deficit refers to the onset of paraplegia or paraparesis after a period of observed normal neurologic function. Delayed-onset neurologic deficit after TAAA repair was first reported in 1988, at which time the condition was considered irreversible and beyond the surgeon's control.⁶³ Since then numerous reports have described improvements in patients' neurologic function by using CSF drainage for delayed-onset neurologic deficits.^{64–66} Delayed neurologic deficit has been observed as early as 2 hours and as late as 2 weeks following surgery (median, 3 days) in 2.7% of patients.⁶⁷ No single risk factor is responsible for delayed neurologic deficit. However, using multivariable analysis, acute dissection, extent II TAAA, and renal insufficiency were identified as significant preoperative predictors for delayed-onset neurologic deficit.⁶⁷ In a subsequent case-control study, postoperative mean arterial pressure of less than 60 mm Hg and CSF drain complications were found to be predictors in the development of delayed-onset neurologic deficit, independent of preoperative predictors⁶⁸ (Fig. 99.16).

As improved spinal cord protection during TAAA surgery has reduced the incidence of neurologic complications, delayed-onset neurologic deficit has emerged as an important clinical entity. The exact mechanisms involved in the development of delayed neurologic deficit remain unknown. It is speculated that delayed neurologic deficit after TAAA repair may result from a "second hit" phenomenon. Adjuncts can protect

FIGURE 99.15. The probability of neurologic deficit increases with clamp time and is markedly higher in patients undergoing thoracoabdominal aortic aneurysm surgery without adjuncts.

FIGURE 99.16. Odds of delayed neurologic deficit by lowest postoperative mean arterial blood pressure, with or without cerebrospinal fluid drain complication. Odds are referenced to one. For example, a patient with a mean arterial blood pressure of 40 mm Hg and a cerebrospinal fluid (CSF) drain complication would have 40:1 odds of delayed neurologic deficit.

the spinal cord intraoperatively and reduce the incidence of immediate neurologic deficit, but the spinal cord remains vulnerable during the early postoperative period. Additional ischemic insults caused by hemodynamic instability, malfunction of the CSF drainage catheter, or both may constitute a “second hit,” causing delayed neurologic deficit. Furthermore, in the rigid, unyielding spinal column, any rise in CSF pressure could lead to an increase in compartment pressure, with consequent decreased spinal cord perfusion. Hence, CSF is drained freely when delayed neurologic deficit develops to relieve the compartment pressure.

To optimize postoperative spinal cord perfusion and oxygen delivery, mean arterial pressure is kept above 90 to 100 mm Hg, hemoglobin above 10 mg/dL, and cardiac index greater than 2.0 L/min. If delayed neurologic deficit occurs, measures to increase spinal cord perfusion are instituted immediately. The patient is placed flat in the supine position. The patency and function of the drain are ascertained at once. If the drain has been removed, the CSF drainage catheter is reinserted immediately and CSF is drained freely until the CSF pressure drops below 10 mm Hg. The systemic arterial pressure is raised, blood transfusion is liberally infused, and oxygen saturation is increased, as indicated earlier. CSF drainage is continued for at least 72 hours for all patients with delayed-onset neurologic deficit. Using this multifaceted approach to treating delayed-onset neurologic deficit, an improvement in neurologic function is seen in 57% of patients.⁶⁷ When the CSF drain was still in place at the onset of delayed neurologic deficit, 75% of patients recovered function; 43% recovered neurologic function if the CSF drain had to be reinserted at the time of the delayed neurologic deficit. Patients who developed delayed neurologic deficit but did not have CSF drainage failed to recover function.

Renal Failure. Acute postoperative renal failure is defined as an increase in serum creatinine of 1 mg/dL per day for 2 consecutive days or by the need for hemodialysis. The reported rate of acute renal failure from large series of patients undergoing TAAA repair falls within the range of 5% to 40% and is associated with mortality rates as high as 70%. Patients who develop acute renal failure more frequently sustain nonrenal complications, such as respiratory failure, central nervous sys-

tem dysfunction, sepsis, and gastrointestinal hemorrhage. For patients who develop postoperative renal failure, early continuous venovenous hemodialysis or daily intermittent hemodialysis is initiated. In the experience of the authors of this chapter, approximately one third of patients who develop acute renal failure remain on hemodialysis, and predictably these patients have a prolonged length of hospital stay. Long-term survival for patients on hemodialysis is dismal. Preoperative chronic renal insufficiency and ruptured aneurysms are known predictors of acute postoperative renal failure. Although the authors of this chapter have theorized that patients with the most extensive extent II TAAA are at highest risk for the development of postoperative renal failure, extent of TAAA has not been shown to be a significant predictor.

The goals of perioperative renal protection are to maintain adequate renal oxygen delivery, reduce renal oxygen utilization, and reduce direct renal tubular injury. However, good strategies to protect renal function during surgical TAAA repair remain elusive. The benefit of cold temperatures for metabolic suppression in organ protection is well known. Local hypothermia has been shown to protect against renal ischemia and reperfusion injury in laboratory animals, and there is some evidence that patients with cold visceral perfusion have superior survival and recovery rates. However, this strategy has not decreased the incidence of acute renal failure. The incidence of postoperative renal failure remains troublesome and the pursuit of an optimal method of renal protection continues to be a top priority.

Glomerular Filtration Rate

Clinically apparent renal insufficiency is a known predictor of 30-day mortality. The overall 30-day mortality was 225 of 1,353 (16%), and the 5-year survival rate was 54%. We are finding increasingly that mortality cannot properly be interpreted without knowledge of preoperative glomerular filtration rate. With normal GFR (>90 mL/min/1.73 m²), 30-day mortality was 6%, while 5-year survival was 77%. With a decline in GFR to the 65 to 90 range, 30-day mortality was 10.6%. Below a GFR of 65, 30-day mortality increases to 26%. Long-term survival stratified by quartile of GFR is shown in Figure 99.17. The effect of GFR on both short-term mortality and long-term survival was highly statistically significant ($p < 0.0001$ for both measures).

Recently, in patients undergoing TAAA repair without apparent renal disease, we have found that calculated glomerular filtration rate is a much stronger predictor for mortality than serum creatinine.⁶⁹ We have used and appraised many different forms of renal protection including distal aortic perfusion, warm blood visceral perfusion, antegrade cold blood visceral perfusion, retrograde cold blood perfusion, and the perioperative use of a renal protective pharmacologic agent, fenoldopam. None of these yielded overly promising results. Using multivariable analyses, we found that preoperative renal failure (creatinine >2.8 g/dL), left renal artery reattachment, visceral perfusion, and the clamp-and-sew technique are predictors of acute renal failure.⁵⁷

In the past, we had used visceral perfusion without cooling or systemic heparin, and this was likely the reason for the negative effect of visceral perfusion on renal protection. We recently reviewed the impact of various adjuncts on renal function. Distal aortic perfusion has emerged as protective but only for aortic repair that does not directly involve the renal arteries. There is evidence, however, that patients treated with cold blood visceral perfusion have superior survival and recovery rates, which may be related to improved liver protection. None of the adjuncts thus far evaluated has clearly prevented acute renal failure. The major predictors of postoperative renal dysfunction remain preoperative renal function, cross-clamp time, and repair extending to the renal arteries.

Excluding patients who had clinically apparent preoperative renal failure, we found that acute renal failure occurred in

FIGURE 99.17. Long-term survival stratified by quartile of glomerular filtration rate.

344 of 1,261 (27.2%) of our patients overall. For patients with preoperative GFR above 90, renal failure was 62 of 367 (17%). When GFR was between 65 and 90, postoperative renal failure was 70 of 310 (23%). At GFRs below 65, renal failure was 212 of 584 (36%). Thirty-day mortality among patients with acute renal failure was 34% compared to 10% mortality for all other patients. Aneurysms involving the visceral vessels (extents II, III, and IV) were much more likely to produce renal failure postoperatively (39 vs. 17%, $p < 0.0001$). Approximately one third of our patients who developed acute renal failure remained on hemodialysis, and long-term survival for patients on hemodialysis has been dismal.

COMPLICATIONS

A summary of complications is shown in Table 99.1. These figures are compiled from a collection of sources.⁷⁰⁻⁸⁰

Elephant Trunk Technique

The authors of this chapter have performed the two-staged elephant trunk procedure in nearly 200 patients with extensive aortic aneurysms.⁸¹ Mortality rates range from 5% to 9% after stage one and 6% to 7% for stage two. During the interval between the two stages (approximately 31 days to 6 weeks), mortality has averaged around 6.5%. When a 5-year follow-up of patients who failed to return for second-stage repair was performed, 32% had died. Although we were unable to determine the exact cause of death for many of these patients, it is likely that a significant number of deaths were a result of aneurysm rupture. Major complications for both stages have been relatively low, with stroke rates of 2% in the first stage and no neurologic deficits in the second. Determining the optimum length of recovery time between stages has been difficult. Because these patients are vulnerable to rupture, it is currently recommended that the second-stage repair be performed after a 4- to 6-week period of recovery.

Impact of Aortic Dissection

Aortic dissection has long been considered a risk factor for neurologic deficit in patients undergoing repair of descending tho-

TABLE 99.1

COMPLICATIONS

COMPLICATION	RESULTS
Early mortality	4%–21%
Immediate neurologic deficit	2%–33%
Delayed neurologic deficit	2%–10%
Acute renal failure—need for dialysis	2%–13%
Acute renal insufficiency	6%–40%
Bleeding—reoperation for bleeding	5%–10%
Vocal cord paralysis/paresis and hoarseness	10%
Cardiac complication—MI, CHF	5%–15%
Pulmonary insufficiency (prolonged ventilation >48 h)	10%–41%
Stroke or transient ischemic attack (reversible)	2%–6%
Gastrointestinal complications (pancreatitis, ischemic colitis, small bowel, cholecystitis, hepatic insufficiency)	7%–10%
Chylothorax	<1%
Hospital length of stay	10–22 days
Survival	1 y = 60%–80% 5 y = 65%–80% 10 y = 40%

CHF, chronic heart failure; MI, myocardial infarction.

racic and TAAAs, particularly during the clamp-and-go era.⁸²⁻⁸⁵ However, in a series of 729 patients operated on for descending thoracic aneurysms and TAAAs, no differences were reported in neurologic outcome between patients with and those without chronic dissection; the rate of paraplegia was 3.6% with dissection versus 4.7% without dissection.⁸⁶ Several factors are likely responsible for the good neurologic outcome of patients with chronic dissection; they include better surgical techniques and anesthetic care, moderate hypothermia, and reimplantation of intercostal arteries. The key element in the improved spinal cord protection, however, has been the use of the adjuncts distal aortic perfusion and CSF drainage.

In acute aortic dissection, the risk of paraplegia following graft replacement of the descending thoracic or thoracoabdominal aorta remains substantial, with a neurologic deficit rate of 32%.⁸⁷ Nevertheless, acute dissection aneurysm patients are usually critically ill, undergoing surgery emergently with little time for preparation. The method of spinal cord protection employed during surgery for acute dissection is often not optimal. In particular, reimplantation of intercostal arteries is ill advised because of the risk of catastrophic bleeding from the friable dissected tissues, and the use of the adjuncts distal aortic perfusion and CSF drainage may not be possible in the presence of hemodynamic instability.

Endovascular Repair

Since the first successful reported thoracic stent graft repair in 1994,⁸⁸ endovascular management of thoracic aortic pathology has evolved at a rapid pace. Thus far, three thoracic aortic devices have received Food and Drug Administration (FDA) approval in the United States. These devices, in the order of approval, are the TAG (WL Gore, Flagstaff, AZ), the Talent Thoracic (Medtronic, Santa Rosa, CA), and the TX2 (Cook,

Bloomington, IN). The results of thoracic endovascular aortic repair (TEVAR) performed in the prospective multicenter trials that led to the FDA approval of these three devices compare favorably to open surgical controls.⁸⁹⁻⁹¹ Although these devices are approved for the treatment of thoracic aortic aneurysms, their off-label use for other thoracic aortic pathology is common. The use of thoracic devices for treatment of a variety of aortic conditions, including acute and chronic type B aortic dissections, traumatic aortic injury, and pseudoaneurysms, has been reported.⁹²⁻⁹⁴ Although the short-term benefits of endovascular therapy are clear, with less morbidity and mortality compared with conventional surgery, the long-term durability of this treatment strategy remains to be determined.

Endovascular treatment of a TAAA would require revascularization of visceral vessels using branched and/or fenestrated devices. There are currently no FDA-approved branched and/or fenestrated devices for TAAA repair available in the United States. The feasibility of a custom-designed investigational device for endovascular TAAA repair has been reported.⁹⁵⁻⁹⁷ Although the early results are encouraging, the technology is rapidly evolving and the widespread adoption of a custom-designed device is challenging. Moreover, a recent study showed no significant difference in mortality or spinal cord ischemia between endovascular and open repair.⁹⁸

In addition to complete endovascular TAAA repair, "hybrid" procedures have evolved. These have combined open debranching procedures with subsequent relining of the aorta with stent grafts. The debranching procedures entail an open retroperitoneal or transperitoneal approach for extra-anatomic bypassing of the visceral and renal arteries from either iliac artery. This is subsequently followed by exclusion of the thoracoabdominal aorta with stent grafts. Although this approach is technically feasible, the risk of mortality remains discouragingly high.⁹⁹⁻¹⁰² Indications for this approach will likely be limited to patients with TAAA who are unfit for open repair and those who are not candidates for endovascular repair (i.e., those with tortuous vessels, inaccessible vessels, or insufficient time to order a customized stent graft). Although much progress has been made in the endovascular repair of TAAAs, the technology is still in its infancy. The next generation of endografts holds a promising future for patients with TAAAs.

Acknowledgments

The authors of this chapter are grateful to G. Ken Goodrick, editor, and to Chris Akers for assistance with the illustrations. The authors would also like to thank Kourosh Keyhani for his contributions to the chapter.

CHAPTER 100 ■ ABDOMINAL AORTIC ANEURYSMS

THOMAS S. HUBER AND W. ANTHONY LEE

KEY POINTS

- 1 An aneurysm is defined as a permanent, focal dilation of an artery that exceeds 1.5 times the normal, expected diameter.
- 2 The risk factors for abdominal aortic aneurysm include age, male gender, smoking, family history, hypertension, and the presence of other aortoiliac or peripheral aneurysms.
- 3 The diameter of an aneurysm is the greatest predictor of rupture as predicted by the tangential stress of the vessel wall.
- 4 The natural history of abdominal aortic aneurysms is to increase in size with a mean growth rate of 0.4 cm/y.
- 5 Computed tomography arteriography is both the diagnostic study of choice and the sole imaging study required for operative planning.
- 6 The treatment of abdominal aortic aneurysm represents a balance between the risk of rupture and the operative mortality rate.
- 7 Infrarenal abdominal aortic aneurysms should be repaired in men when the diameter reaches 5.5 cm and in women when the diameter reaches 5.0 cm provided they are a reasonable operative risk.
- 8 Endovascular aneurysm repair mandates long-term follow-up with serial imaging to confirm the integrity of the device and repair.
- 9 Randomized trials have not demonstrated an advantage for the endovascular approach, but it appears to be the preferred choice by both patients and providers in the United States.

Abdominal aortic aneurysms are a common problem in developed countries and represent a significant public health concern. Operative repair is the only means to reduce the risk of rupture and the associated mortality. The treatment algorithm represents a balance between the risk of operation and the future risk of rupture. The open technique has been the traditional approach since its description by Dubost et al.¹ in the early 1950s. The endovascular approach has emerged as the preferred treatment since its commercial release at the turn of the century and has truly revolutionized the care of patients with abdominal aortic aneurysms.

DEFINITIONS AND CLASSIFICATIONS

- 1 An aneurysm is defined as a permanent, focal dilation of an artery that exceeds 1.5 times the normal, expected diameter.² The diameter of a normal abdominal aorta in an adult male is approximately 2 cm (range, 1.4 to 3.0 cm), and, therefore, a 3-cm aorta would be considered aneurysmal.³ The abdominal aorta is consistently larger in men than in women and increases slightly with age in both sexes.⁴ Abdominal aortic aneurysms should be differentiated from other conditions in which the size of the aorta is increased, including ectasia and arteriomegaly. In aortic *ectasia*, the diameter is increased by less than 50% of the normal expected diameter. The term *arteriomegaly* refers to a diffuse (nonfocal) enlargement of several arterial segments with increases in diameter greater than 50% of the normal expected diameter. Arterial segments in patients with arteriomegaly may be considered aneurysmal if the diameter of a segment is increased by more than 50% of the diameter of an adjacent segment. The term *aneurysmosis* denotes the presence of multiple aneurysmal segments separated by either normal, occluded, or arteriomegaly segments.

Abdominal aortic aneurysms are classified primarily according to how far they extend cephalad (Fig. 100.1). More than 95% of all abdominal aortic aneurysms are classified as

infrarenal.⁵ These aneurysms start below the orifices of the renal arteries and usually have a 1.5- to 2-cm proximal segment of normal (i.e., nonaneurysmal) aorta. Approximately 10% to 20% of all abdominal aortic aneurysms are associated with aneurysms of the iliac arteries.^{6,7} Aneurysmal involvement of the iliac vessels is usually confined to the common or internal iliac arteries; aneurysmal involvement of the external iliac arteries is extremely rare. The management of abdominal aortic aneurysms associated with common iliac artery aneurysms is similar to the management of abdominal aortic aneurysms alone, and these two patterns should be considered basically the same disease process. The only significant difference in the decision algorithm is the configuration of the graft for open repair (i.e., tube vs. bifurcated) and the site of the distal anastomoses. Aneurysms classified as juxtarenal extend to the level of the renal arteries, and those classified as suprarenal extend to the level of the superior mesenteric or celiac arteries. Aneurysms involving the thoracic and abdominal aorta are designated as thoracoabdominal aortic aneurysms and are classified (extent 1 through 4) according to how far they extend both cephalad and caudal. Aneurysms that extend above the renal arteries are more complicated to repair and associated with greater morbidity as might be predicted from the obligatory periods of renal and mesenteric ischemia.

MAGNITUDE OF THE PROBLEM

Abdominal aortic aneurysms and their sequelae are common problems in developed countries. The incidence of abdominal aortic aneurysms in the United States ranges from 1.5% in autopsy series to 3.2% among unselected adult patients screened with ultrasonography.⁵ Predictably, the incidence increases among subsets of patients with defined risk factors for abdominal aortic aneurysms and approximates 50% among patients with either femoral or popliteal artery aneurysms.⁵ It should be emphasized that these rates have been determined with the broad definition of an aneurysm (i.e., 1.5 times the normal vessel diameter) and do not necessarily reflect aneurysms that are of

FIGURE 100.1. Classification of abdominal aortic aneurysms. More than 95% of all abdominal aortic aneurysms are infraarenal. Juxtarenal aneurysms extend cephalad to the level of the renal arteries, and supraarenal aneurysms to the level of the superior mesenteric and/or celiac arteries. Aneurysms involving the thoracic and abdominal portions of the aorta are designated as thoracoabdominal aortic aneurysms and are classified (extent 1 through 4) according to how far they extend cephalad and caudal.

sufficient size to merit repair. Furthermore, the incidence of abdominal aortic aneurysms appears to be increasing and this likely reflects an increase in the “true” incidence rather than simply an increase in detection, diagnosis, or the aging population.⁸ A total of 14,751 deaths were caused by abdominal aortic aneurysms and/or dissections during 2003 and this corresponded to death rate of 5.1 per 100,000 as reported by the Centers for Disease Control and Prevention.⁹ Notably, these numbers may be underestimates because a significant number of sudden deaths in elderly patients may be secondary to undiagnosed ruptured aneurysms.

PATHOGENESIS AND RISK FACTORS

The pathogenesis of abdominal aortic aneurysms remains unresolved, although it is an intense area of both experimental and clinical investigation. Multiple potential etiologic factors have been implicated including atherosclerosis,¹⁰ hemodynamics,¹¹ collagen,¹² collagenase,¹³ elastin,¹⁴ elastase,¹⁵ metalloproteinases,¹⁶ protease inhibitors,¹⁷ programmed cell death (apoptosis),¹⁸ neutrophils,¹⁹ and inflammatory mediators.²⁰

The etiology is likely multifactorial with interaction between both environmental and genetic factors. Unfortunately, investigation into the potential mechanisms has not resulted in any effective therapies. Elucidation of the pathogenesis has been complicated by the older age of patients at presentation and the absence of suitable animal models.

2 Multiple risk factors have been identified for the development of abdominal aortic aneurysms and include age, sex, smoking, hypertension, hyperlipidemia, peripheral vascular disease, myocardial infarction, and family history.^{21–24} Identification of these risk factors is important to facilitate screening high-risk patient populations. Abdominal aortic aneurysms are a disease process of the elderly and are rare among persons younger than 50 years of age. Indeed, the mean age among patients undergoing repair across the country was 72 ± 7 years (\pm standard deviation [SD]) in a recent series comprising a 20% national sample.²⁵ A meta-analysis of the population-based screening studies for abdominal aortic aneurysms reported that male sex had the strongest association (odds ratio, 5.69).²¹ The incidence of death resulting from abdominal aortic aneurysms for men 60 to 64 years of age is 11-fold higher than that for women of the same age, but it is only three-fold higher for men between 85 and 90 years of age. Furthermore, men account for approximately 80% of all abdominal aortic aneurysm repairs performed nationally.²⁵ The Aneurysm Detection and Management Veterans Affairs Cooperative Study Group (ADAM) reported that smoking was the strongest modifiable risk factor associated with abdominal aortic aneurysms greater than 4 cm (odds ratio, 5.57) among the 73,451 veterans screened.²⁶ Similarly, Wilmsink et al.^{26,27} reported that abdominal aneurysms were 7.6 times more likely to develop in current smokers than in nonsmokers and that the duration of smoking rather than level of exposure appeared to correlate with their development. Darling et al.²⁸ prospectively analyzed patients undergoing repair of abdominal aortic aneurysms and reported that 15.1% had a first-degree relative with an aneurysm, in contrast to only 1.8% in the control group. Interestingly, the presence of a female family member with an aneurysm correlated with an increased risk for rupture. Larsson et al.²⁹ reported from a population-based control study in Sweden that the relative risk of an abdominal aortic aneurysm in first-degree relatives was 1.9 (95% confidence interval [CI], 1.6–2.2). However, the risk of an aneurysm was not affected by the gender of the index individual or relative.

The presence of an aneurysm in the aortic, iliac, femoral, or popliteal arteries dramatically increases the risk for a new or additional abdominal aortic aneurysm. In patients undergoing abdominal aortic or iliac artery aneurysm repair, there is a 5% to 15% chance that an additional aneurysm will develop that merits another repair.^{30,31} This second aneurysm may develop anywhere in the remaining native aorta, commonly within the residual infraarenal aortic cuff. The incidence of aortoiliac aneurysms in patients with popliteal or femoral artery aneurysms is approximately 50%.⁵ Importantly, all patients found to have one of these peripheral artery aneurysms should undergo a computed tomography scan (CT) of the entire aorta and iliac vessels to exclude a synchronous aneurysm in addition to being screened for other peripheral aneurysms. Interestingly, the reverse scenario is not true; patients with aortic or iliac artery aneurysms have a less than 5% chance of having a peripheral artery aneurysm, and evaluation beyond physical examination is likely not justified.³²

The incidence of abdominal aortic aneurysm is increased among patients with an aortic dissection and among patients with heart transplants. Late or repeated operations are required in approximately 20% of patients by 10 years after an acute aortic dissection.³³ The aneurysms may develop in either the thoracic or abdominal aorta, although the former site is more common. The term *dissecting aneurysm* is frequently used to describe bland aneurysms, although it is a misnomer; dissection and aneurysmal degeneration are separate processes.

Simply, a dissection is a tear within the aortic wall itself that extends for a variable length resulting in “true” and “false” lumen. The prevalence of abdominal aortic aneurysms and the rate of expansion are both increased among heart transplant patients.^{34–36} The responsible mechanisms remain unclear, but the obligatory chronic immunosuppression may contribute. Interestingly, several transplant centers have initiated screening programs as part of their pretransplant evaluation.

It is notable that the risk factors for abdominal aortic aneurysm are similar to those associated with the development of atherosclerosis with the noted exception of diabetes mellitus.^{22,23} Furthermore, atherosclerotic changes are found almost universally within the abdominal aorta at the time of repair. However, the processes of atherosclerosis and aneurysmal degeneration are likely separate and distinct. Simplistically, atherosclerosis is a process that leads to a narrowing of the vessel lumen, whereas aneurysmal degeneration leads to dilation. Aneurysms have historically been referred to as *atherosclerotic aneurysms*, although this is also a misnomer that has been appropriately replaced by the term *nonspecific aneurysms*.

PRINCIPLES OF MANAGEMENT

The treatment goals for patients with abdominal aortic aneurysms are to prolong life, relieve symptoms, and prevent rupture. Because surgical treatment is the only effective means to achieve these goals, the crucial question that must be answered is whether the patient merits operative repair. The decision algorithm is straightforward for patients with ruptured or symptomatic aneurysms, but more difficult for patients with asymptomatic, intact aneurysms. The decision to recommend operative intervention in the elective setting is contingent on the balance between the risk of operation and the risk of expectant or non-operative management within the context of the patient’s desires or wishes. Appropriate assessment of these risks requires an understanding of the size-associated risk for rupture, the growth rate, and the mortality associated with repair. However, it should be emphasized that repair of an asymptomatic, intact aneurysm is a prophylactic operation.

Understanding the natural history of untreated abdominal aortic aneurysms requires knowledge of the physics associated with the vessel wall. The tangential stress (*t*) of a fluid-filled cylindric tube is determined by the following equation:

t = Pr/d

where *P* is the pressure exerted by the blood (dyne/cm²), *r* is the internal radius (cm), and *d* is the thickness (cm) of the arterial wall.³⁷ The tangential stress of a cylinder 0.2 cm thick with an internal radius of 0.8 cm and a fluid pressure of 150 mm Hg is 8 × 10⁵ dyne/cm² (Fig. 100.2). An increase in the internal radius (diameter) of the cylinder to 2.94 cm and a concomitant decrease in the wall thickness, as might occur with an aneurysm, would increase the tangential stress to 98 × 10⁵ dyne/cm². Thus, a threefold increase in diameter would result in a 12-fold increase in the tangential stress. Aneurysms rupture when the tangential stress exceeds the tensile strength of the vessel wall. It should be emphasized that the tangential stress varies directly with the radius of the cylinder (vessel) but is independent of its length.

3 The diameter of an abdominal aortic aneurysm is the greatest predictor of rupture as would be predicted by the tangential stress of the vessel wall. The diameter of an aneurysm is determined by measuring its greatest diameter from outer wall to outer wall in any orientation (i.e., anterior to posterior, transverse) throughout the extent of the aneurysm. These measurements may be confounded by the tortuosity of the vessel, so every attempt should be made to obtain a cross-sectional measurement perpendicular to the long axis. The collective annual rupture risks per aneurysm diameter are shown in Table 100.1.³⁸ Although there is some variability in the data, it

FIGURE 100.2. Cross-sectional view of a 2-cm-diameter cylinder that expands to a diameter of 6 cm while the wall cross-sectional area remains constant. Expansion of a 1-cm-diameter cylinder to a diameter of 3 cm with no change in wall cross-sectional area increases wall tensile stress 12-fold. *t*, wall stress; *d*, wall thickness; *r_i*, inside radius; *r_o*, outside radius.

is generally appreciated that the rupture risk for aneurysms less than 5 cm in diameter is small, but increases considerably for those greater than 5.5 cm. These data may be simplified by using the rule of thumb that the annual rupture risk is 5% or less for a 5-cm aneurysm, 10% for a 6-cm aneurysm, and 20% for a 7-cm aneurysm. These numbers correspond to an estimated 5-year rupture risk of 50% for 6-cm aneurysms and 100% for those 7 cm. Notably, both the ADAM²⁶ and UK Small Aneurysm Trial,³⁹ which randomized patients with small aneurysms (4.0 to 5.5 cm) to open repair or surveillance, reported that the rupture risk for surveillance was 1% or less per year.

A variety of other factors have also been reported to increase the risk of aneurysm rupture including female gender,^{40–42} chronic obstructive pulmonary disease (COPD),^{40,43} smoking,⁴⁰ hypertension,^{40,43} family history,⁴⁴ and wall stress.⁴⁵ Notably, the UK Small Aneurysm Trial reported that the rupture risk was increased for female gender (hazard ratio, 3.0), current smoking (hazard ratio, 1.5), severe COPD

AAA, abdominal aortic aneurysm.
From Brewster DC, Cronenwett JL, Hallett JW Jr, et al. Guidelines for the treatment of abdominal aortic aneurysms. Report of a subcommittee of the Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery. *J Vasc Surg* 2003; 37:1106–1117.

(hazard ratio, 0.6 per liter forced expiratory volume in 1 second [FEV₁]), and higher mean arterial pressure (hazard ratio, 1.2 per mm Hg). Fillinger et al.⁴⁶ used finite element analysis to calculate the wall stress of abdominal aortic aneurysms and reported that the wall stress of symptomatic/ruptured aneurysms exceeds those for elective aneurysms. The impact of the aneurysm growth rate on rupture risk remains unclear and has been difficult to separate from aneurysm diameter alone.⁴² However, an aneurysm expansion of greater than or equal to 1 cm/y is generally considered worrisome and a potential risk factor for rupture.

4 The natural history of abdominal aortic aneurysms is to increase in size. The reported mean rate of growth has varied from 0.2 to 0.3 cm/y in population studies^{47–49} to 0.4 cm/y from referral practices,^{50–52} with the latter figure (0.4 cm/y) generally quoted as a reasonable estimate. Several factors including female gender, current smoking, and larger original diameter have been associated with an increased rate of growth as might be predicted from the risk factors for rupture.^{47,49,53} Interestingly, doxycycline and coenzyme A (CoA) reductase inhibitors (i.e., statins) may inhibit aneurysm growth.^{53,54} It should be emphasized that these growth rates are mean values and that all aneurysms do not grow in a linear fashion as might be predicted. The growth curve may be somewhat erratic or “staccato,” with no growth detected during consecutive 6-month intervals followed by a growth of 0.6 cm during the next one.⁵⁵ Furthermore, it should be emphasized that the past rate of growth does not predict future events; patients should not be lulled into a false sense of security if their aneurysm is relatively stable over time.

The mortality rate associated with repair of an abdominal aortic aneurysm depends on the status of the aneurysm (intact/asymptomatic, intact/symptomatic, ruptured) and the method of repair (open vs. endovascular). A recent population study from the Nationwide Inpatient Sample reported that the operative mortality rate for *open repair of intact* aneurysms in the United States was 4.2%.²⁵ Predictably, the operative mortality rate increased with age, ranging from 2.2% among persons 50 to 59 years of age to 9.2% among those older than age 80. Interestingly, the operative mortality rate was significantly higher among women (6.1% vs. 3.7%). Similar reports from other regional and national databases have consistently reported mortality rates less than 5% for the open repair of intact aneurysms.^{56–58} The mortality rate for open repair in the randomized trials comparing operative repair with surveillance for small aneurysms (UK Small Aneurysm Trial, 5.8%; ADAM, 2.7%) and open repair with endovascular repair (Dutch Randomized Endovascular Aneurysm Management [DREAM] Trial, 4.6%; Endovascular Aneurysm Repair [EVAR] Trial, 4.6%)^{59,60} are within the range of these nationwide series. Furthermore, a literature review examining the mortality rate of open abdominal aortic aneurysm repair encompassing 64 individual studies reported a collective rate of 5.5%.⁶¹

The reported operative mortality rate for *endovascular repair of intact* abdominal aortic aneurysms has been consistently less than those for the open approach.^{56–58,62–65} Lee et al.⁶⁶ reported from the Nationwide Inpatient Sample that the operative mortality rate for endovascular repair was 1.3% in 2001. Similarly, Schermerhorn et al.⁵⁸ reported that the operative mortality after endovascular aneurysm repair was 1.2% among Medicare beneficiaries during 2001–2004. Early results from the DREAM Trial⁵² and the EVAR Trial⁵⁹ comparing open and endovascular repair have reported that the perioperative mortality rate is lower for endovascular repair and within the same range (DREAM, 1.2% vs. 4.6%; EVAR, 1.7% vs. 4.7%).

The operative mortality rate for *open repair of intact/symptomatic* aneurysms among patients undergoing emergent repair exceeds that for elective repair and has ranged from 9% to 19%.^{5,67,68} Various explanations have been proposed for this increased mortality rate relative to that for intact/asymptomatic

aneurysms including failure to maximize preoperative medical conditions, increased incidence of inadvertent venous injuries, and less experienced operative teams, although the true explanation remains unclear. It is notable that the increased rate has been fairly consistent in the literature, in contrast to the mortality rate for intact/asymptomatic aneurysms, which has gradually decreased. Comparable data are not available for the *endovascular repair of intact/symptomatic* aneurysms, although the mortality rates are likely similar to those considered asymptomatic.

The actual mortality rate for ruptured abdominal aortic aneurysms is somewhat difficult to determine because a significant number of sudden deaths in elderly patients are likely secondary to ruptured aneurysms. It has been estimated that 50% of all patients with ruptured abdominal aortic aneurysms die outside the hospital, and that approximately 50% of those who actually undergo open repair do not survive.⁵ Indeed, a recent meta-analysis spanning 50 years and 77 studies reported that the operative mortality rate for the *open repair of ruptured* aneurysms was 48%.⁶⁹ These figures correspond to an overall mortality rate of approximately 80%, although this may be an underestimate. It is remarkable that the optimization of pre-hospital and emergency room care, including a reduction in the mean transfer time from the emergency department to the operating room to 12 minutes, has not resulted in a decrease in the mortality rate of ruptured aneurysms.⁷⁰ Notably, the operative mortality rate for ruptured aneurysms treated with the open approach has improved slightly over the past few decades, with Bown et al.⁶⁹ reporting a 3.5% reduction per decade.

The mortality rate for the *endovascular repair of ruptured* abdominal aortic aneurysms appears to be lower than that associated with the open approach.^{71–76} Rayt et al.⁷⁴ reported a collective mortality rate of 24% for the endovascular approach from 31 studies encompassing 982 patients, while other meta-analyses or systematic reviews have reported comparable rates.^{72,75} The potential to treat ruptured abdominal aortic aneurysms with the endovascular approach may represent the greatest contribution or benefit of the technology. However, further validation is necessary since the reports cited previously likely reflect both patient selection and publication bias. Notably, Giles et al.⁷⁷ reported that the annual number of deaths across the country from both intact and ruptured aneurysms has decreased significantly since the introduction of the endovascular approach.

CLINICAL PRESENTATION AND DIAGNOSIS

The overwhelming majority of abdominal aortic aneurysms are asymptomatic at the time of discovery. Most aneurysms are detected by abdominal or pelvic imaging studies, such as ultrasonography and CT, performed for other indications (e.g., chronic back pain, renal cysts) rather than on physical examination. Indeed, it is often difficult to feel an abdominal aortic aneurysm on physical examination because of its anatomic location in the posterior abdomen, and these difficulties are exacerbated in the presence of truncal obesity. A recent literature review examining the accuracy of physical examination reported that the sensitivity ranged from 33% to 100%, the specificity ranged from 75% to 100%, and the positive predictive value ranged from 14% to 100%.⁷⁸ Given these fairly broad ranges, the authors concluded that physical examination could not be relied upon to exclude an abdominal aortic aneurysm. Predictably, the accuracy of primary care physicians for detecting abdominal aortic aneurysms in patients with known aneurysms is only fair because of the limitations noted earlier and the failure to actually palpate the aorta during the physical examination. Intact abdominal aortic and iliac artery

aneurysms may present with symptoms that lead to further investigation and the correct diagnosis, although this is the exception rather than the rule. Enlargement of the aneurysm may cause vertebral erosion and chronic back pain. Additionally, thrombosis of an abdominal aortic aneurysm may cause acute ischemia in the lower torso, and aneurysms may be a source of arterial macroemboli or microemboli leading to acute ischemia of a lower extremity or digit, respectively.

Patients with intact/symptomatic or ruptured aneurysms present with abdominal or back pain related to the aneurysm itself. The etiology of the pain is unclear, but may be secondary to local nerve compression. The character of the pain is variable and ranges from dull to sharp. The pain is usually acute in onset and persistent. It may be superimposed on more chronic abdominal or back pain, but the presentation is usually not subtle, and the pain can be differentiated from more chronic complaints. Additionally, the pain may radiate from the abdomen to the back, flank, inguinal region, or genitalia. Approximately 10% of patients with ruptured abdominal aortic aneurysms present with signs and symptoms similar to those of ureteral colic or other acute urologic problems.⁷⁹ Indeed, the diagnosis of a ruptured aneurysm must be ruled out in a timely fashion in patients presenting with testicular pain who have a normal urinalysis and testicular examination.

Patients with a ruptured abdominal aortic aneurysm may present anywhere along the spectrum from hemodynamically stable to profound shock. Their status depends on the ability of the tissues adjacent to the aorta to tamponade the bleeding and their physiologic status. If the adjacent tissues effectively tamponade the bleeding, the patient may present in a hemodynamically stable state with essentially normal vital signs. However, it should be emphasized that this is usually a temporary situation, and health care providers should not be lulled into a false sense of security. A ruptured abdominal aortic aneurysm is a true medical emergency that requires immediate operative repair regardless of the patient's hemodynamic status. Furthermore, the vital signs may be misleading because patients can lose up to 15% of their blood volume (class 1 shock) without any appreciable change in their pulse rate or blood pressure. If the aneurysm ruptures freely into the peritoneal space, patients usually exsanguinate before they can seek medical attention.

Patients with a ruptured abdominal aortic aneurysm may also present with either an aortoenteric or an aortocaval fistula, although both are relatively rare. Patients with an aortoenteric fistula may present with massive intestinal bleeding. The aorta may rupture through any portion of the bowel, although the duodenum and proximal small bowel are the most common sites. The overwhelming majority of aortoenteric fistulas result from the erosion of a prosthetic graft into the adjacent bowel (secondary aortoenteric fistula) rather than from unrepaired aneurysm (primary aortoenteric fistula). However, the diagnosis of an aortoenteric fistula must be ruled out in all patients with gastrointestinal bleeding and either an abdominal aortic aneurysm or a previous infrarenal aortic reconstruction. Patients with an aortocaval fistula present with high-output congestive heart failure, a continuous abdominal bruit, and edema of the lower extremities. The severity of the heart failure symptoms depends on the size of the fistula and the magnitude of the systemic shunt.

Several imaging studies are available to establish or confirm the diagnosis of an abdominal aortic aneurysm. Indeed, the introduction of endovascular techniques for aneurysm repair has resulted in an evolution of these modalities. The generic imaging goals for patients with an abdominal aortic aneurysm are to establish the diagnosis, determine the presence of rupture, determine the cephalad/caudal extent of the aneurysm, determine the feasibility of endovascular repair, appropriately size the aneurysm and access vessels for endovascular repair, screen for other visceral pathology, and screen for the presence of anatomic variants that would complicate operative repair,

5 such as a left-sided vena cava or a horseshoe kidney. Although

FIGURE 100.3. B-mode ultrasonogram showing a transverse view of an infrarenal abdominal aortic aneurysm. Note the vessel wall and the large quantity of intraluminal clot surrounding the smaller, blood-filled center (dark circle).

no imaging study satisfies every objective, ultrasound has emerged as the ideal *screening* study, with CT arteriography being the definitive *diagnostic* test and the preferred modality for operative planning.

Abdominal ultrasound is a safe, simple, and inexpensive means of detecting abdominal aortic aneurysms (Fig. 100.3). It is relatively inexpensive and does not require the use of ionizing radiation, intravenous contrast, or arterial cannulation. Furthermore, the ultrasound units are portable and almost universally available in the hospital setting, including the emergency room.⁸⁰ The sensitivity of ultrasound for detecting abdominal aortic aneurysms is good, and the technique is reproducible within 0.3 cm.⁸¹ However, the technique is somewhat operator dependent and potentially confounded by the presence of bowel gas. Ultrasound can accurately image the infrarenal aorta to its bifurcation but is less reliable for imaging the portions of the aorta proximal to the renal arteries and distal to the iliac vessels. Furthermore, it is not as reliable as CT for differentiating a ruptured from an intact aneurysm. It is an excellent tool for screening patients at high risk for an abdominal aortic aneurysm and for confirming the presence of an aneurysm suspected by physical examination or clinical presentation. Furthermore, it is a useful technique to follow patients with small aneurysms (<4 cm) when the exact measurement is not crucial. It should not be used to confirm the diagnosis of a ruptured aneurysm, nor should it be used as the sole imaging study before elective repair because it does not provide a complete image of the aorta and iliac arteries.

CT arteriography overcomes many of the limitations of ultrasound and represents the current “gold standard” for imaging patients with abdominal aortic aneurysms (Fig. 100.4). The technique is more expensive than ultrasound, not universally available, and potentially harmful because of the ionizing radiation and intravenous contrast. Indeed, the evolution of endovascular aneurysm repair and the requisite follow-up imaging studies have focused increased attention on the magnitude of the radiation injury. It is worth noting that the radiation dose associated with an abdominal CT scan is 10 millisieverts, while that for a routine chest radiograph is only 0.1 millisieverts. The incidence of allergic reactions to the contrast may be reduced by a steroid preparation, while the potential nephrotoxicity can be reduced by acetylcysteine or sodium

FIGURE 100.4. Computed tomography scan demonstrates a large abdominal aortic aneurysm. Note that the majority of the lumen is filled with contrast.

bicarbonate.^{82,83} These potential risks can be avoided altogether by not using contrast. However, the quality of the non-contrast images is less than optimal. CT is very sensitive for detecting both intact and ruptured aneurysms, and the images are reproducible within 0.2 cm.⁸¹ The quality of the CT images has continued to improve with each new generation of scanners, and the image acquisition times have decreased. Currently, it is possible to image the aorta and iliac vessels from the ascending arch to the femoral vessels during a routine aneurysm scan with an image acquisition time of less than 45 seconds. CT arteriograms have essentially replaced traditional catheter-based diagnostic arteriograms. It is possible to reconstruct the axial CT images into three-dimensional (3D) images using special software and obtain images perpendicular to the centerline blood flow (Fig. 100.5). These 3D CT images have dramatically improved the accuracy and consistency of sizing for endovascular repair.⁸⁴ CT is also helpful for detecting other intra-abdominal pathology or anatomic variants that may impact the operative approach. Specific concerns include the location of the left renal vein and other associated venous anomalies, the location and size of the kidneys, and the characteristics of the aneurysm wall. CT is currently the sole diagnostic test performed before open surgical repair in the majority of cases and the imaging study of choice to confirm or refute the diagnosis of a ruptured abdominal aortic aneurysm. Additionally, CT is the serial imaging study of choice when aneurysms exceed 4 cm and approach the threshold for operative intervention.

Both magnetic resonance imaging (MRI) and catheter-based arteriography have been used as diagnostic imaging studies for patients with abdominal aortic aneurysms. The image quality and overall sensitivity of MRI is comparable to CT, but the technology is not as widely available and most surgeons are less familiar with interpreting the images. Furthermore, the technique is relatively contraindicated for patients with ferromagnetic devices (e.g., pacemakers, joints), and imaging critically ill patients is cumbersome, if not prohibitive. Aneurysms are frequently diagnosed during catheter-based arteriography, although this should not be viewed as a diagnostic test. An arteriogram only delineates the lumen of the vessels (i.e., aortic, iliac, and femoral arteries). Abdominal aortic aneurysms are frequently filled with laminated thrombus and have a fairly normal-appearing lumen. Importantly, the “lumenogram” produced by the contrast reflects the patent

FIGURE 100.5. Three-dimensional computed tomography scan of the aorta and the iliac, femoral, and visceral arteries is shown. Note the infrarenal abdominal aortic aneurysm that extends to the aortic bifurcation.

lumen rather than the “true” lumen of the vessel (and the actual size of the aneurysm). Preoperative catheter-based arteriography was formerly performed before endovascular repair to help select the appropriate-size device. Furthermore, it was considered helpful in the subset of patients undergoing open repair who had aortoiliac occlusive disease, poorly controlled hypertension/renal insufficiency, chronic mesenteric ischemia, and/or renal anomalies, including horseshoe kidneys. These concerns and indications are still relevant, but CT arteriography has largely supplanted any role for the catheter-based approach and avoids the additional inherent risks and cost.

The diagnostic approach and initial treatment for patients with a potential ruptured aneurysm merit further comment. Because of the high attendant mortality rate, prompt diagnosis and emergent repair are necessary. In a study from the Cleveland Clinic Vascular Registry, the operative mortality rate associated with ruptured abdominal aortic aneurysms increased from 35% when the initial diagnosis was correct to 75% when incorrect.⁸⁵ Admittedly, the clinical presentation may be confusing, and delays in diagnosis are not uncommon. The classic triad of hypotension, abdominal pain, and a pulsatile abdominal mass was present in only 50% of patients with ruptured aneurysms in a single institutional series.⁸⁶

Elderly patients who present to the emergency room in a hemodynamically *unstable* state with abdominal or back pain require emergent exploratory laparotomy in most cases. The potential causes of shock (i.e., hypovolemic, cardiogenic, septic, neurogenic) can usually be quickly differentiated by a brief history and physical examination. However, this clinical scenario is most suggestive of hypovolemic or hemorrhagic shock resulting from an intra-abdominal catastrophe. The differential diagnosis is extensive and includes pancreatitis, mesenteric infarction, acute Addisonian crisis, and rupture of a visceral artery aneurysm in addition to rupture of an abdominal aortic

FIGURE 100.6. Contrast computed tomography scan demonstrates a ruptured abdominal aortic aneurysm. Note the large retroperitoneal hematoma and the loss of the normal fat plane anterior and lateral to the left psoas muscle.

aneurysm. A myocardial infarction can mimic a ruptured aneurysm in this patient population and potentially confounds the diagnosis, although it can usually be confirmed by the findings on electrocardiogram. Additional diagnostic imaging has not traditionally been considered necessary in this setting and, indeed, has been considered potentially harmful due to the obligatory delay in getting patients to the operating room. Due to the dramatic reduction in CT acquisition times and the potential feasibility of endovascular repair, abdominal/pelvic CT scans are likely indicated in this scenario to confirm the diagnosis and plan the operative procedure, provided it can be performed expeditiously. This approach has the added advantage of reducing the number of negative laparotomies in critically ill patients. A recent natural history study of patients with ruptured abdominal aortic aneurysms not offered operative repair reported that fewer than 15% of the patients died within 2 hours of hospital admission.⁸⁷ Based on these findings, the authors concluded that most patients with ruptured aneurysms are sufficiently stable to undergo a CT scan, and this opinion has been echoed by a recent systemic review examining the role of endovascular aneurysm repair for ruptured aneurysms.⁷⁵ Several findings on CT are suggestive of a ruptured abdominal aortic aneurysm including disruption of the calcium ring within the aortic wall, disruption of the aortic margins, retroperitoneal hematomas, mass lesions in the psoas region, displacement of the kidneys, abnormal soft tissues posterior to the aorta, effacement of the normal fat planes between the aorta and adjacent viscera, and abnormal retroperitoneal fluid collections (Fig. 100.6). Patients undergoing an emergent CT arteriogram to rule out a ruptured abdominal aortic aneurysm should not receive oral contrast because of the obligatory delay associated with administration and its confounding effects on the arteriogram or the imaging of the vessels.

The diagnosis of a ruptured abdominal aortic aneurysm should be considered in elderly patients who present to the emergency room hemodynamically *stable* with abdominal or back pain. Admittedly, the differential diagnosis for abdominal or back pain in this patient population is extensive, and the incidence of a ruptured abdominal aortic aneurysm is small. An expeditious history and physical examination can usually determine the cause of the pain. A pulsatile abdominal aortic mass, an unexplained low hematocrit, or hemodynamic instability before presentation is particularly worrisome and

increases the level of suspicion. The diagnosis of an abdominal aortic aneurysm may be confirmed with a portable abdominal ultrasound in the emergency room.⁸⁰ Indeed, the current trauma algorithms include abdominal ultrasound as a diagnostic technique for blunt trauma, and many centers have ultrasound units assigned to the emergency room. If ultrasound confirms the diagnosis of an aneurysm, further evaluation with CT should be obtained to rule out rupture. Alternatively, a CT may be obtained as the sole imaging study. Any findings consistent with a ruptured aneurysm on CT mandate direct transfer to the operating room and immediate repair. Aggressive fluid resuscitation should be avoided and mild hypotension (i.e., systolic pressure >80 mm Hg) tolerated in conscious patients due to the theoretical potential to cause the aneurysm to rupture into the peritoneal cavity and/or release the tamponade effect of the retroperitoneal tissue. If an intact aneurysm is found on CT without any suggestion of rupture, the next logical question is whether the aneurysm is the source of the pain. Symptomatic aneurysms are likely associated with an increased risk of rupture, although the natural history remains poorly defined. Patients with symptomatic/intact aneurysms greater than or equal to 5 cm in diameter should be admitted to a monitored setting and scheduled for urgent operative repair, usually the following day, provided no additional causes for the pain are identified. Additional sources of the abdominal pain should be sought in patients with aneurysms smaller than 4 cm in light of the small rupture risk. The appropriate treatment for patients with aneurysms 4 to 5 cm is less clear. These aneurysms have the potential to rupture, although the risk is small. It is recommended that these patients be admitted and the source of their pain further investigated. However, urgent operative repair is recommended if no additional causes are identified.

The role of screening for abdominal aortic aneurysms in asymptomatic patients has been partially clarified. The U.S. Preventative Task Force has issued a position statement advocating a single screening ultrasound in males 65 to 75 years of age who have a smoking history.⁸⁸ These recommendations were based on the results of a best-evidence systematic review that identified four population-based, randomized, controlled trials demonstrating that screening resulted in a reduction of aneurysm-related mortality.⁸⁹ Notably, the Preventative Task Force stated that the literature did not substantiate screening for women even among those with a family history and stated that the harms of screening outweighed the risks. Screening for abdominal aortic aneurysms in this subset of elderly men has been shown to be both cost effective⁹⁰ and comparable to other screening programs in adult patients.⁹¹ Despite the Preventative Task Force's recommendations, screening should likely be extended to other high-risk patient populations including patients with a first-degree relative with an abdominal aortic aneurysm, those with evidence of a peripheral artery aneurysm, and those undergoing evaluation for heart transplantation. Medicare currently pays for a single screening ultrasound as part of the Welcome to Medicare physical examination for men who have smoked sometime during their life and for both men and women with a family history of abdominal aortic aneurysms. Interestingly, Kim et al.⁹² predicted that the introduction of a national screening program would reduce the number of emergent aneurysm repairs while increasing the number of elective repairs. They estimated that this would translate into two additional elective repairs per month for a typical district, general hospital, while saving 11 abdominal aortic aneurysm-related deaths per year.

OPERATIVE INDICATIONS

All patients with symptomatic or ruptured abdominal aortic aneurysms should undergo operative repair unless they have an underlying medical condition, such as metastatic cancer, that precludes long-term survival or their quality of life is not

sufficient to justify the intervention. The latter situation entails a difficult decision, but not offering operative repair should be considered in certain cases (e.g., a debilitated, demented patient in a nursing home) after the family has been consulted.

The operative decision-making process for intact/asymptomatic abdominal aortic aneurysms is a complex one that needs to be tailored to the individual patient. Indeed, there is no single parameter that merits repair. The operative indications are contingent on the size of the aneurysm, life expectancy, comorbidities, preference, and anatomic configuration. It is important to remember that the repair of an intact/asymptomatic abdominal aortic aneurysm is a prophylactic operation that represents a balance between the operative risk and the future risk of rupture with the ultimate treatment goals to prolong life, relieve symptoms, and prevent rupture.

The diameter of the abdominal aortic aneurysm is the best predictor of rupture as stated earlier and has been used as the most common indication for repair. There has been a change in the diameter-based operative criteria within the past few decades, although this has been clarified more recently with level 1 evidence. It is interesting to note that the diameter threshold for good-risk patients has decreased from 6 cm to as low as 4 cm with latter recommendation from the guidelines of the national vascular surgical societies.⁸¹ Both the UK Small Aneurysm Trial³⁹ and the ADAM Trial²⁶ concluded that it was safe to follow patients with 4.0- to 5.5-cm aneurysms and that early operation did not confer any long-term survival benefit. As noted earlier, the rupture risk for patients in the surveillance group was less than 1% per year. It is important to note that more than 60% of the patients in both studies ultimately underwent operative repair despite their initial randomization. A longer-term follow-up study from the UK Small Aneurysm Trial extending to 12 years did not demonstrate a survival benefit for the patients assigned to early surgery.⁹³ However, it is important to note that almost all of the patients who survived ultimately required repair since their aneurysms continued to grow and exceed the 5.5-cm threshold. Indeed, the relevant question may not be whether patients with small aneurysm need to be repaired, but rather when they need to be repaired. In a separate publication from the UK Small Aneurysm Trial, Brown et al.⁴⁰ reported that the rupture risk for women was over fourfold higher, as noted earlier, suggesting that the 5.5-cm-diameter threshold for repair may be too high for women. The proponents of smaller-diameter-based thresholds for repair (i.e., <5.5 cm) have justified their approach stating that even small aneurysms rupture, aneurysms continue to increase in diameter and will likely need to be repaired, the patients' medical conditions will likely deteriorate with age, and the operative mortality/morbidity rate for small aneurysms may be less. Although the level 1 evidence does not support this lower threshold, it is important to note that the size discrepancy between a 5.2-cm and 5.5-cm aneurysm is very small and likely within the resolution of the imaging study.

The presence of medical comorbidities predictably impacts the perioperative mortality rate and threshold for repair. Steyerberg et al.⁹⁴ identified several independent risk factors for operative mortality during open repair (Table 100.2), and these have remained consistent throughout the literature. Similarly, Beck et al.⁵⁶ developed a predictive model for both open and endovascular repair using a prospective registry from several northeastern states. They reported that chronic obstructive pulmonary disease, suprarenal aortic clamp, renal insufficiency, and advanced age (≥ 70) were predictive of mortality at 1 year after open repair, with the mortality ranging from 1% to 67% depending on the number of risk factors. Congestive heart failure and larger aneurysm diameter (≥ 6.5 cm) were the only predictive factors after endovascular repair, with the mortality ranging from 4% to 23%. The consistent, dramatic impact of renal insufficiency was further emphasized by a national series that reported a ninefold increase in mortality.

TABLE 100.2

TREATMENT

INDEPENDENT RISK FACTORS FOR OPERATIVE MORTALITY AFTER ELECTIVE ABDOMINAL AORTIC ANEURYSM REPAIR

RISK FACTOR	ODDS RATIO	95% CI
Creatinine >1.8 mg/dL	3.3	1.5–7.5
Congestive heart failure	2.3	1.1–5.2
ECG ischemia	2.2	1.0–5.1
Pulmonary dysfunction	1.9	1.0–3.8
Older age (per decade)	1.5	1.2–1.8
Female gender	1.5	0.7–3.0

CI, confidence interval; ECG, electrocardiogram.

From Steyerberg EW, Kievit J, de Mol Van Otterloo JC, et al.

Perioperative mortality of elective abdominal aortic aneurysm surgery.

A clinical prediction rule based on literature and individual patient data. *Arch Intern Med* 1995;155(18):1998–2004.

Notably, the estimated glomerular filtration rate may be a better index of renal function than serum creatinine and, therefore, likely a better predictor of adverse outcome. Life expectancy is inseparable from comorbidities, but it should be emphasized that the average life expectancy for a 60-year-old and 85-year-old man in the United States is 18 and 5 years, respectively.⁹⁵

Patient preference should be factored into the operative decision-making process. Although the level 1 evidence suggests that it is safe to follow abdominal aortic aneurysms until they reach the 5.5-cm threshold, patients may not be willing to accept this small, finite risk and desire to have their aneurysm repaired at a lower threshold. Indeed, patients often echo the justification for early repair proposed by surgeons.

The anatomic configuration of the aneurysm and/or the associated structures should factor into the operative decision-making process. Any technical factors that complicate the repair likely increase the perioperative mortality/morbidity including the need for suprarenal clamp application due to the obligatory renal/visceral ischemia, venous anomalies (e.g., left-sided vena cava), renal anomalies (e.g., horseshoe kidney), and inflammatory aneurysms. Admittedly, many of these technical concerns are relevant only to the open approach and can be overcome/avoided by endovascular repair provided that it is an option from an anatomic standpoint.

The introduction of the endovascular approach has challenged the operative indications for intact/asymptomatic aneurysms. Indeed, the significant decrease in the perioperative mortality rate reported in both the DREAM⁵² and EVAR Trials⁵⁹ appear to justify lowering the threshold. However, it is important to note that the rupture rate for aneurysms less than 5.5 cm in the UK Small Aneurysm³⁹ and ADAM²⁶ Trials was less than 1% per year, which is still lower than the perioperative mortality rate for endovascular repair reported from DREAM,⁵² EVAR,⁵⁹ and most of the national databases.^{57,58,66} Similarly, Finlayson et al.⁹⁶ used a decision analysis model to determine the optimal diameter for open and endovascular aneurysm repair and concluded that the endovascular approach lowers the operative threshold only for older patients in poor health.

The Joint Council of the American Association for Vascular Surgery and the Society for Vascular Surgery have released updated guidelines for the treatment of patients with abdominal aortic aneurysms that address the concerns highlighted earlier.³⁸ They recommend that a diameter of 5.5 cm is an appropriate threshold for repair in the “average patient” with an intact infrarenal aneurysm, but emphasize the importance of individualizing each case. They state that rapid aneurysm

expansion (>1 cm/y), symptoms related to the aneurysm, and female gender merit repair at a smaller diameter, while consideration should be given to earlier repair in young patients provided that the operative mortality rate is acceptable. Furthermore, they recommend that a larger-diameter threshold is appropriate in higher-risk patients and emphasize that there does not appear to be any justification to alter the operative threshold for the endovascular approach. A reasonable approach, and one that we have adopted in our own practice, is to use 5.5 cm as a threshold for repair in men and 5.0 cm for women.

7

Patients who do not meet the threshold for operative repair should be followed closely. It is important to educate the patients about their underlying disease process and emphasize the importance of long-term follow-up. Notably, Valentine et al.⁹⁷ reported that 32% of patients with small aneurysms managed by “watchful waiting” were noncompliant with their follow-up plan. Furthermore, it is important to counsel patients about the presence of symptoms associated with rupture and the importance of seeking urgent medical attention. Recent guidelines have suggested that patients with aneurysms less than 3 cm in diameter should be reimaged at 5 years, while those with aneurysms between 3.0 and 3.4 cm should be reimaged at 3 years and those with aneurysms between 3.5 and 3.9 cm should be reimaged at 1 year.⁹⁸ Aneurysms greater than 4.0 cm should likely be reimaged every 6 months. As noted previously, abdominal ultrasound is likely the most appropriate imaging study for aneurysms less than 4.0 cm, with CT more appropriate above that threshold. It is important to note that up to 50% of the patients deemed a prohibitive operative risk and not offered elective repair will ultimately die from a ruptured aneurysm.^{99–103} These patients who are not candidates for elective repair should not be offered emergent repair in the event that their aneurysm ruptures or becomes symptomatic.

CHOICE OF OPEN OR ENDOVASCULAR REPAIR

After the decision to recommend operative repair has been made, the technique for the repair needs to be determined. Admittedly, these decisions are somewhat interrelated since the decision to recommend operative repair in certain subsets of patients is oftentimes contingent upon whether they are candidates for the endovascular approach. The past two decades have witnessed a rapid evolution of the endovascular technique, and, indeed, this evolution has helped define our discipline. It has been clearly demonstrated that the technical success rates for endovascular graft repair are excellent and the need for intraoperative conversion to open repair negligible. The perioperative events and midterm outcomes have been defined by level 1 evidence. Many of the technical limitations inherent to the earlier endovascular devices and anatomic limitations have been overcome. Despite the lack of definitive long-term outcome data, the endovascular approach for treatment of abdominal aortic aneurysms has been widely applied. Indeed, 56% of all aneurysm repairs in the United States during 2005 were performed using the endovascular approach.⁷⁷ The choice of open or endovascular repair is complicated and contingent upon several factors including feasibility, outcome, comorbidities, compliance, cost, and preference. It is imperative that these issues, including their respective advantages/disadvantages or strengths/weaknesses, be addressed with the patients during the decision process to ensure proper informed consent.

The initial determinant of the approach is the anatomic configuration of the aorta, the aneurysm, and the access vessels. The commercially available endovascular devices come in a finite range of sizes and, thus, are suitable only if specific anatomic conditions are satisfied. Although the number of available devices and their specific characteristics are con-

stantly evolving, the “generic” endograft consists of a fabric graft (i.e., polyester or expanded polytetrafluoroethylene) and a metallic endo/exoskeleton (i.e., stainless steel or nitinol) that facilitates proximal/distal fixation by the radial force of the stent (Fig. 100.7). In some devices, the proximal fixation is augmented by the presence of suprarenal hooks. The “generic” devices are modular and consist of either two (main body and contralateral iliac limb) or three (main body, contralateral iliac limb, and ipsilateral iliac limb) components with a variety of additional ancillary pieces that allow proximal or distal extensions at the aortic and iliac ends, respectively. The initial experiences with aorto-aortic or “tube graft” configurations were unsuccessful due to problems with the distal landing site at the aortic bifurcation and have been abandoned. Indeed, the current strategy is to seat the proximal component of the bifurcated system as close to the lowest renal artery as possible and the distal components as close to the iliac bifurcation as possible. Although there is some variability among the commercially available devices in terms of their specific sizes and anatomic constraints, the general anatomic requirements are similar. The infrarenal abdominal aorta must have a suitable, nonaneurysmal landing zone for the endograft, while the diameter of the aorta at that location should be greater than or equal to 15 mm in length and greater than or equal to 17 to 19 mm, but less than or equal to 26 to 32 mm in diameter (ranges reflect differences between the commercial devices). Furthermore, the proximal neck angle should be less than or equal to 45 degrees as measured by the intersection of the centerline of the infrarenal aorta at the landing zone site and the centerline of the aneurysm through the aortic bifurcation. The infrarenal neck should be relatively free of thrombus and calcification to facilitate a seal at the implantation site. It is notable that neck length requirements have increased from greater than or equal to 1 cm to greater than or equal to 1.5 cm since release of the original devices at the turn of the century. Indeed, the longer the infrarenal neck length and, therefore, the longer the device seal zone, the better. The iliac artery should have a suitable landing zone greater than or equal to 20 mm with an associated diameter between 7 and 20 mm to facilitate both anchoring the graft and passing the main device into the aorta. The distal landing zone for the iliac limbs is usually in the common iliac artery, although the anatomic constraints with regard to the size of the access vessels and the introduction of the devices are relevant for both the common and external iliac vessels.

The percentage of patients who are anatomic suitable for an endograft remains unresolved and is likely contingent upon the nature of the individual surgeon/institution practice and the available devices. This percentage of suitable patients has been highly variable with reports of 30% in a nationwide series,¹⁰⁴ 55% in a regional series,¹⁰⁵ and 14% to 66% in institutional series.^{106–108} Notably, the reasons cited for exclusion include a short infrarenal neck (54%), inadequate iliac vessels (47%), and a wide infrarenal neck (40%).¹⁰⁶

A variety of techniques have been described to overcome the anatomic limitations of the endovascular approach, thereby extending its feasibility. Indeed, some modification has been described to overcome almost every anatomic contraindication. Stenoses within the access vessels can be overcome by dilation (i.e., balloon angioplasty, serial dilators) or by the use of a prosthetic conduit.¹⁰⁹ The prosthetic conduit is usually anastomosed to the bifurcation of the common iliac artery and then tunneled through the retroperitoneal space below the inguinal ligament. Alternatively, an aortouniiliac endograft can be configured and a femorofemoral bypass performed. Notably, the patency rates of the femorofemoral bypass graft in this setting have been reported to be excellent.^{110,111} Aneurysmal degeneration of the common iliac artery can be overcome by a variety of techniques including simply using larger-diameter graft limbs, using an aortic extension as a cuff (i.e., “bell bottom” technique), occluding/embolizing the internal iliac artery and seating the iliac limb in the external iliac

FIGURE 100.7. The commercially available endografts are shown: (A) AneuRx; (B) Excluder; (C) Zenith. All three are similar and consist of a fabric graft (polyester or expanded polytetrafluoroethylene) and a metallic exoskeleton (stainless steel or nitinol) that facilitate proximal/distal fixation by radial force with or without hooks. They are modular devices consisting of either two (main body and contralateral iliac limb) or three (main body, contralateral iliac limb, and ipsilateral iliac limb) components with a variety of additional ones that allow proximal or distal extensions at the aortic and iliac ends, respectively.

artery, or bypassing the internal iliac artery and seating the iliac limb in the external iliac artery. Although relatively simple to perform, internal iliac artery embolization has been associated with a moderate incidence of complications including buttock/thigh claudication (30% to 40%), sexual dysfunction, neurologic deficit/paraplegia, pelvic ischemia, and gluteal compartment syndrome.^{112,113} The claudication improves with time in the majority of patients but can be quite debilitating, particularly in patients who did not claudicate preoperatively. Many of the other complications, although somewhat rare, are irreversible and can be catastrophic. Because of these concerns, bilateral internal iliac artery occlusion/embolization should likely be avoided. Bypass of the internal iliac artery overcomes many of these limitations and has been associated with excellent results in terms of long-term graft patency,

although the procedure is somewhat challenging and adds significantly to the overall magnitude of the “less invasive” procedure.¹⁰⁹ Unfortunately, extending the indications for endovascular repair beyond those recommended by the manufacturers (i.e., instructions for use [IFU]) has been associated with an increase in the incidence of adverse events including decreased survival and a higher need for reintervention.¹¹⁴

Consideration of the perioperative and long-term outcomes after endovascular aneurysm repair requires introduction of the concepts of endoleak and endotension. Simply, endoleak is the perfusion of the aneurysm sac outside the lumen of the endograft, while endotension is the persistent pressurization within the excluded aneurysm sac. Endoleaks have been classified as types 1 through 4 based on the mechanism of the leak (Fig. 100.8). Type 1 leaks originate at either the proximal or

FIGURE 100.8. The various endoleaks are demonstrated. **A:** Type 1 leaks originate at either the proximal or distal attachment sites. Note the large blush of contrast outside of the graft lumen at the proximal fixation site. **B:** Type 2 leaks are from the collateral circulation originating in the lumbar or inferior mesenteric arteries. Note the contrast-filled limbs of the graft and the rim of contrast outside the limbs of the graft, but within the lumen of the aorta. The other computed tomography images demonstrated that the leak originated from the inferior mesenteric artery. **C:** Type 3 leaks are caused by fabric tears or problems at the graft interfaces of the modular devices. Note the contrast blush outside of the lumen of the graft at the modular interface. **D:** Type 4 leaks are usually transient (<24 hours) trans-graft extravasations and can result from the porosity of the graft and needle holes.

distal attachment sites. Type 2 leaks come from branch vessels such as the lumbar or inferior mesenteric arteries. Type 3 leaks are caused by fabric tears or problems at the graft interfaces of the modular devices, whereas type 4 leaks are usually transient (<24 hours) trans-graft extravasations that result from the porosity of the graft and needle holes. It should be emphasized that the entire concept of an endoleak is predicated on the ability to detect contrast or blood flow outside the lumen of the endograft and is, therefore, contingent on the sensitivity and specificity of the various imaging techniques. The major concern about both endoleaks and endotension is that the pressure transmitted to the aneurysm wall may cause the aneurysm to expand and/or rupture. The clinical significance of the various endoleak types is different. Both type 1 and 3 endoleaks are considered major adverse outcomes associated with an increased risk of rupture, and they merit urgent/emergent treatment.¹¹⁵ Type 2 endoleaks are generally considered less worrisome in terms of their rupture risk, although they are associated with an increased risk for reintervention.¹¹⁵ They can generally be followed with serial imaging studies, but merit evaluation/intervention if the aneurysm sac continues to enlarge. Type 4 endoleaks are self-limited and benign. The clinical significance of endotension is likewise unresolved. Indeed, the concept itself is somewhat ambiguous given the limitations of actually measuring the pressure within the aneurysm sac. It should be noted that freedom from endoleak does not necessarily mean freedom from endotension given the observation that aneurysms can continue to enlarge in the absence of an identifiable endoleak.¹¹⁶

The *perioperative* complication rates appear to be lower after endovascular repair. As noted earlier, the randomized controlled DREAM and EVAR Trials reported a significant decrease in the perioperative mortality rate (DREAM, 1.2% vs. 4.6%; EVAR Trial, 1.7% vs. 4.7%).^{59,60} The EVAR Trial also reported a trend toward a decrease in the combined operative mortality/severe complication rate (9.8% vs. 4.7%, $p = 0.10$). Multiple clinical trials have reported that the overall major complication rates after both endovascular and open repair are approximately 15%, although the magnitude of the complications is less for the endovascular approach and primarily includes vascular access complications (e.g., hematoma, femoral artery injury).¹¹⁷ These clinical trials have likewise demonstrated that the total hospital length of stay, intensive care unit length of stay, operative blood loss, and time necessary to resume normal activities are all lower for the endovascular approach.¹¹⁷ Additionally, Hua et al.⁵⁷ reported from the private-sector National Surgical Quality Improvement Project (NSQIP) database that the perioperative complication rate after endovascular repair was 24%. Interestingly, the impact on sexual function remains unresolved. A survey of the DREAM participants demonstrated that sexual dysfunction was common after both endovascular and open repair, but returned to the baseline state at 3 months for both groups.¹¹⁸ In contrast, Xenos et al.¹¹⁹ reported significantly less orgasmic and erectile dysfunction after endovascular repair.

The midterm results after the EVAR and DREAM Trials have failed to document any significant benefit for the endovascular approach in terms of almost every outcome measure analyzed.^{120,121} Somewhat surprisingly, there was no difference in all-cause mortality at 2 years in the DREAM Trial (survival: open, 89.6%; EVAR, 89.7%) or at 4 years in the EVAR Trial (mortality: open, 29%; EVAR, 26%). There were significant differences in terms of aneurysm-related mortality at these time points, although the differences were fairly minimal and their relevance suspect. Both the complication rates (EVAR, 41%; open, 9%) and costs (EVAR, £13,257; open, £9,926) were significantly greater for the endovascular approach, while there were negligible differences in the quality of life assessments.^{120,122,123}

The midterm results from the DREAM and EVAR Trials have been somewhat sobering, and longer-term outcomes are

necessary to further define the role of the endovascular approach. It is clear that the endovascular approach is not as secure a repair as the traditional, open alternative. The endovascular repair is associated with ongoing rupture risk that likely approaches 1% per year.^{117,124} Notably, Schermerhorn et al.⁵⁸ reported a 1.8% rupture risk among Medicare patients undergoing endovascular repair between 2001 and 2004. The rupture risk has been associated with poor patient selection, operator error, unrecognized/untreated endoleaks, large aneurysms, and device migration.^{117,125} Interestingly, the mortality rate associated with rupture after endovascular repair may be less than for de novo ruptures.¹²⁶ Approximately 10% to 20% of patients develop an endoleak during the first year after endovascular repair.^{127–129} Admittedly, not all of these require remediation. The excluded aneurysms can continue to grow and, thereby, represent a risk for rupture. This has been correlated not only with the presence of endoleak as noted earlier but also with the specific device and the baseline aneurysm size.^{130,131} Some type of structural failure including fabric tears, hook fractures, and suture breakage has been reported for almost every device. Design modifications have been implemented to overcome many of these deficiencies, although they represent an ongoing concern that may not be manifest for years. As a consequence of all these potential limitations, reintervention is necessary in about 15% of the patients per year.^{58,128} The majority of these remedial procedures are catheter based with the risk of open conversion approximately 1% to 2% per year.¹²⁴ Unfortunately, the perioperative complication rate for conversion likely exceeds that for open repair as might be predicted given its complexity. It is important to emphasize that open aneurysm repair is associated with a small incidence of graft-related complications and need for remedial procedures. Approximately 2% of patients undergoing open repair require reintervention within the first 5 years,³⁸ while graft-related complications and graft-related deaths have been reported in 15% and 2% of patients, respectively, at 15 years.^{58,132}

The presence of significant comorbidities and advanced age favors the endovascular approach. Although the operative threshold in regard to the aneurysm diameter measurement is the same, the endovascular approach may allow a subset of patients not considered suitable candidates for an open operation to have their aneurysms repaired. Indeed, endovascular aneurysm repair has been shown to be feasible in patients with hepatic insufficiency¹³³ and consistently safe in octogenarians.^{134,135} However, a modicum of clinical judgment is necessary. It is important to reemphasize that abdominal aortic aneurysm repairs are prophylactic operations and that not every patient merits treatment. The EVAR Trial 2 randomized patients not fit for open repair to expectant management or endovascular repair and demonstrated no difference in aneurysm-related mortality, all-cause mortality, or quality of life.¹²² Notably, the patients were truly “high risk,” with a perioperative mortality rate of 9% and a 4-year mortality rate of almost 40%. Despite the potential nephrotoxicity associated with iodinated contrast, chronic renal insufficiency is not an absolute contraindication to endovascular repair. Strategies to reduce the associated risk can be employed including the administration of acetylcysteine and sodium bicarbonate.^{82,83} Alternatively, the procedure can be performed without contrast altogether by using intravascular ultrasound. Unfortunately, chronic renal insufficiency is a significant risk factor for adverse outcome after both open and endovascular repair. Furthermore, multiple studies have shown that both approaches are associated with a decrement of renal function.^{136–139} The endovascular approach may be associated with a greater decrement of function postoperatively, but the findings are somewhat equivocal; suprarenal fixation of the endovascular device does not seem to be associated with a greater decrement.¹³⁹

8 The known device-related complications and the uncertainty about the long-term outcome after endovascular repair mandate indefinite surveillance. It is imperative that patients comply with the prescribed protocol, and their ability or desire

to fulfill these expectations should be factored into the specific choice of procedure. It is important to note that although the incidence of complications declines with the number of negative postoperative CT scans, new endoleaks have been discovered out as far as 7 years. Similarly, it is imperative that all surgeons who offer endovascular aneurysm repair provide conscientious, long-term follow-up.

The cost comparisons between the open and endovascular approach have been somewhat inconclusive, although the endovascular approach is likely more expensive. Clearly, the EVAR-1, and EVAR-2 Trials have demonstrated that the endovascular approach was more expensive.^{120,122} The shorter hospital length of stay and lower incidence of major complications associated with the endovascular approach have predictably resulted in a reduction in some of the hospital costs. However, these have been offset by increases in other hospital-related costs, with the cost of the device itself representing the single largest item. Notably, Sternbergh and Money¹⁴⁰ reported that the cost of the device accounted for 52% of the total cost of the endovascular repair and estimated that the costs of open and endovascular repair were \$12,546 and \$19,985, respectively, in the AneuRx Phase II clinical trial. Analysis of the hospital costs and reimbursement associated with endovascular repair among seven medical centers (university hospital, three; community hospital, four) demonstrated a net loss of \$2,162.^{140,141} However, others have reported that the contribution to the hospital margin on a daily basis may be superior for endovascular repair given the associated shorter duration of stay that permits higher throughput, fuller overhead amortization, and better use of inpatient beds.¹⁴² It is important to note that most of the analyses have focused on the hospital- and device-related costs, but have failed to include the associated professional fees and the costs associated with long-term follow-up that may be quite substantial. Kim et al.¹⁴³ reported that reimbursement for the endovascular repair is not sufficient for the long-term surveillance and secondary procedures. Indeed, it has been reported that the overall cost of endovascular repair may be twice that of the open approach.¹¹⁷

9 Despite the various advantages and disadvantages of the approaches outlined previously, patients and providers seem to prefer the endovascular approach, and these preferences appear to be one of the driving forces for the widespread application of the technique. Indeed, it is uncommon for patients who are candidates for either approach to elect open repair. Notably, Williamson et al.¹⁴⁴ reported that 18% of all patients undergoing open repair would not undergo the procedure again. The potential to perform the endovascular repair completely percutaneously (i.e., no femoral artery exposure) clearly adds to the appeal of the approach.^{145,146} It is interesting to note that these patient preferences may not be sustained. A follow-up study from the DREAM Trial reported that patients undergoing endovascular repair had a better quality of life initially, but those undergoing open repair had a better quality at 6 months and beyond.¹¹⁸

The proverbial “bottom line” for the open versus endovascular debate remains unresolved. The Joint Council of the American Association for Vascular Surgery and the Society for Vascular Surgery have recommended that endovascular repair is most appropriate for patients at increased risk for open repair because of its uncertain long-term durability and need for surveillance.³⁸ The subset of patients at increased risk includes older, sicker patients and those with other mitigating anatomic concerns such as the proverbial “hostile abdomen.” The recommendations further emphasize that extending the limits of the endovascular approach to patients who are poor anatomic candidates increases the incidence of adverse outcome. Similarly, the Agency for Healthcare Research Quality conducted an evidence-based review and concluded that endovascular repair for aneurysms greater than 5.5 cm did not improve patient survival or health status relative to open repair despite the fact that the perioperative outcomes were

improved.¹⁴⁷ Furthermore, they reported that the endovascular approach was associated with increased cost, complications, need for surveillance, and need for remedial procedures. Lastly, they concluded that it did not provide a benefit for patients unfit for open repair.

OPERATIVE REPAIR

Preoperative Evaluation

The preoperative evaluation of patients undergoing elective abdominal aortic aneurysm repair is similar to that of patients undergoing any major general or vascular surgical procedure. Patients undergoing endovascular repair should likely undergo the same preoperative workup despite the perception that associated perioperative stresses are less. All patients should receive a complete history and a physical examination, an electrocardiogram, and a chest radiograph. Routine laboratory studies, including a complete blood cell count with platelets, serum electrolytes/creatinine, and coagulation studies, should be obtained. A specimen should be sent to the blood bank and the appropriate quantity of blood products cross matched. This number can be determined from the historic operative transfusion requirements obtained from the blood bank, but usually 2 to 4 units of packed red blood cells are sufficient. A thorough peripheral pulse examination should be included in the physical examination and validated with formal ankle-brachial indices. The anesthesiologist should see the patients preoperatively, and a bowel preparation with mechanical lavage should be performed the day before surgery. Additionally, patients should be started on a beta-blocker, an aspirin, and a statin (3-hydroxy-3-methylglutaryl [HMG]-CoA reductase inhibitors) agent if they are not already on them. The American College of Cardiology (ACC)/American Heart Association (AHA) Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery recommend that the beta-blockers should be given to vascular surgery patients who are at high cardiac risk and probably should be given to those undergoing vascular surgery with more than one clinical risk factor (risk factors: coronary artery disease, congestive heart failure, cerebral vascular occlusive disease (CVOD), diabetes mellitus, chronic renal insufficiency).¹⁴⁸ Furthermore, the ACC/AHA Guidelines recommend that patients undergoing vascular surgery should be on a statin. Notably, a recent study demonstrated that statins were associated with a decreased incidence of perioperative mortality and nonfatal myocardial infarction after aneurysm repair.¹⁴⁹ Indeed, all patients with atherosclerotic cardiovascular disease should likely be on aspirin, beta-blockers, a lipid-lowering agent, and an angiotensin-converting enzyme (ACE) inhibitor long term as part of the AHA/ACC Guidelines for Preventing Heart Attack and Death in Patients with Atherosclerotic Cardiovascular Disease.¹⁵⁰

All active medical problems, including abnormalities identified during the preoperative evaluation, should be controlled as well as possible before elective aneurysm repair. However, extensive diagnostic testing is probably unnecessary. Routine pulmonary function tests and measurement of arterial blood gases are not indicated, although they may be beneficial in selected patients with advanced chronic obstructive pulmonary disease.¹⁵¹ The presence of chronic obstructive pulmonary disease often complicates postoperative ventilator management, but it is unusual for a patient's pulmonary disease to be sufficiently severe to preclude operation.¹⁵² Similarly, timed urine collections for creatinine clearance and other assessments of renal function have not proved beneficial despite the dramatic impact of preoperative renal insufficiency on perioperative outcome, although it may be beneficial to calculate the estimated glomerular filtration rate.

The appropriate cardiac workup before abdominal aortic aneurysm repair is evolving and is somewhat institution

dependent. This controversy has been further complicated by the publication of the Coronary Artery Revascularization Prophylaxis (CARP) Trial that examined the role of coronary artery revascularization before major vascular surgery among patients with significant coronary artery disease.¹⁵³ Notably, the study reported that preoperative coronary artery revascularization did not reduce the incidence of either perioperative myocardial infarction or long-term mortality. It is important to emphasize that the overall objective of the preoperative cardiac workup is to optimize the cardiovascular system and thereby reduce both the perioperative and long-term risk of myocardial infarction and death. Admittedly, the prevalence of coronary artery disease among patients undergoing abdominal aortic aneurysm repair is quite high. Hertz et al.,¹⁵⁴ in a landmark publication, reported that 25% of 1,000 patients undergoing evaluation for peripheral vascular surgery (cerebral vascular occlusive disease, lower extremity arterial occlusive disease, abdominal aortic aneurysm) had severe, surgically correctable lesions detected during cardiac catheterization; 6% had severe, uncorrectable disease; and only 8% had no evidence of disease. Interestingly, the incidence of surgically correctable disease was highest among patients undergoing evaluation for abdominal aortic aneurysm. The most recent edition of the ACC/AHA Guidelines have simplified the preoperative evaluation before elective vascular procedures.¹⁴⁸ Briefly, patients with active cardiac conditions (unstable coronary syndromes, decompensated congestive heart failure, significant arrhythmias, and significant valvular disease) should be seen in consultation by a cardiologist. Patients with good functional capacity as defined by the ability to generate at least 4 metabolic equivalents (METs, 4 METs = ability to walk up a flight of stairs) can undergo major vascular procedures without additional testing. Those patients that cannot generate 4 METs and have at least three clinical risk factors (see earlier) should be considered for further cardiac testing if the results will change the clinical management. Notably, there is insufficient evidence to support a reduced cardiac workup for patients undergoing endovascular repair.¹⁵⁵ It is important to emphasize that although the cardiac risk of endovascular repair may be less, the subset of patients undergoing the procedure are often older and sicker.

All patients should undergo some type of imaging modality as part of their preoperative evaluation to confirm the diagnosis and plan the procedure. Indeed, determining whether a patient is an endovascular candidate and appropriately sizing the device depend on the anatomic measurements obtained at the time of imaging. A CT arteriogram of the chest, abdomen, and pelvis is the optimal imaging study to visualize the aneurysm and is the only one required in most cases. Abdominal ultrasonography is insufficient as the sole imaging study before aneurysm repair in light of its inability to accurately define the cephalad extent of the aneurysm and the involvement of the iliac vessels.

Open Repair of Intact Abdominal Aortic Aneurysms

Technique. A significant amount of preparation is required in the operating room before making the incision, and this preparation needs to be coordinated among the surgical and anesthetic teams for both the open and endovascular approach. Although the decision about the choice of anesthesia is deferred to the anesthesiologists, inhalation agents and an endotracheal tube are used most frequently. Adjunctive epidural anesthesia may improve postoperative pain control¹⁵⁶ and may be beneficial in patients with severe pulmonary disease.¹⁵⁷ Adequate intravenous access should be established to facilitate resuscitation. Central venous access is usually obtained although not necessary. Electrocardiographic leads,

an arterial catheter, and a Foley catheter should be placed for continuous monitoring of the electrocardiogram, arterial pressure, and urine output, respectively. Additionally, a nasogastric tube should be inserted. A Swan-Ganz pulmonary artery catheter or a transesophageal echocardiogram probe should be inserted in patients with significant cardiac disease. However, routine use of pulmonary artery catheters in patients undergoing aortic surgery is not recommended and may be associated with a higher rate of intraoperative complications.^{158,159} Peripheral arterial pulses should be interrogated with either palpation or continuous wave Doppler ultrasound and marked to facilitate confirmation after restoration of lower extremity perfusion. Strategies to maintain core body temperature should be initiated.^{158,160} Specifically, the room temperature should be increased, warming devices should be attached to all intravenous infusion lines, and either a recirculating alcohol blanket or forced-air blanket should be applied. Bush et al.¹⁶¹ reported that hypothermia (<34.5°C) during abdominal aortic aneurysm repair was associated with multiple physiologic derangements and adverse outcomes. Use of an intraoperative autologous transfusion device should be considered. However, a recent meta-analysis of five randomized controlled trials reported that there is insufficient evidence to recommend its use during vascular surgery, including aortic surgery.¹⁶² These devices should likely be used when a significant amount of blood loss is anticipated such as during suprarenal or thoracoabdominal aortic aneurysm repairs. Furthermore, they can be helpful in patients who object to blood transfusions on religious principles. An extensive operative field from “nipples to toes” should be prepared with the use of topical antimicrobial agents. A first-generation cephalosporin or vancomycin should be administered prior to the incision.

Abdominal aortic aneurysms may be repaired through several different incisions or approaches including midline, retroperitoneal, or transverse (supraumbilical straight, infraumbilical straight, infraumbilical curvilinear, bilateral subcostal). The incisions or approaches must be viewed as complementary since neither is perfect for every clinical scenario. Indeed, surgeons should be familiar with the various approaches and select the optimal one for the clinical setting. The determinants of the incision include the cephalad/caudal extent of the aneurysm, body habitus, presence of prior abdominal incisions, presence of abdominal wall stomas, comorbidities, additional intraoperative pathology, inflammatory aneurysms, renal anomalies, requirements for concomitant procedures, urgency of aortic control, and surgeon preference. The midline approach is preferable for patients with ruptured abdominal aortic aneurysms because aortic control at the level of the diaphragm can be obtained rapidly. The bilateral subcostal approach provides the best exposure and is the incision of choice for obese patients, those with extensive iliac artery aneurysms, those requiring concomitant renal artery revascularization, and those with juxtarenal aneurysms that require suprarenal aortic control. The retroperitoneal approach is optimal for patients with multiple previous abdominal incisions (“hostile abdomen”), abdominal wall stomas, suprarenal aneurysms, inflammatory aneurysms, and horseshoe kidneys. However, the retroperitoneal approach is limited by the inability to assess the intraperitoneal structures and the limited access to the right renal artery and right iliac vessels. It was previously contended that the retroperitoneal approach posed less of a physiologic insult than the transperitoneal approach and, therefore, was ideal for patients with advanced pulmonary or cardiac disease. However, this has not been supported by a prospective randomized trial.¹⁶³ A detailed description of the retroperitoneal approach is beyond the context of this chapter but is available in most standard vascular surgical texts.

The sequence of steps used to repair an intact, infrarenal abdominal aortic aneurysm after a bilateral subcostal incision can be summarized (Fig. 100.9). The abdomen is explored after the peritoneal cavity is entered, and both the gallbladder and colon are carefully examined. The lower abdominal wall

FIGURE 100.9. Steps involved in the standard repair of an infrarenal abdominal aortic aneurysm extending into the proximal common iliac arteries. **A:** The proximal duodenum is mobilized and the retroperitoneum overlying the aorta incised. The infrarenal aorta immediately below the renal vein is dissected. The iliac bifurcations are exposed, and vascular clamps are applied to the infrarenal aorta and distal common iliac arteries after adequate heparinization. A longitudinal arteriotomy is extended from the infrarenal aorta onto the right common iliac artery. **B:** Back-bleeding from the lumbar arteries is controlled with figure-of-eight sutures. The proximal anastomosis is performed in an end-to-end configuration below the renal arteries. The distal anastomoses are performed at the common iliac bifurcation beyond the aneurysmal segments. The left limb of the graft is tunneled through the intact left common iliac aneurysm shell. **C:** The residual aneurysm shell is closed over the prosthetic graft, and the retroperitoneum is reapproximated to prevent erosion of the graft into the overlying bowel.

flap is immobilized to either the drapes or the pubic towel with the use of penetrating towel clips. The small bowel is manually retracted laterally to the right, and the duodenum is mobilized by incising the ligament of Treitz. The inferior mesenteric vein may be suture-ligated at this juncture to facilitate exposure. The tissue adjacent to the inferior mesenteric vein should be palpated to rule out a large, meandering mesenteric artery. This artery is an important visceral collateral and should be preserved. The retroperitoneum over the aorta is incised with electrocautery, and the left renal vein is exposed. Self-retaining Buckwalter retractors are then placed to facilitate further exposure. The small bowel is placed in a bowel bag, eviscerated, and retracted laterally to the right with the aid of malleable retractors for the Buckwalter. The transverse colon and superior abdominal wall flap are retracted cephalad while the lower abdominal wall is further retracted caudal. The aorta immediately inferior to the renal arteries is exposed and both renal arteries visualized. The infrarenal aorta at this location is dissected circumferentially to facilitate placement of a transverse aortic clamp. However, this step may be omitted if a vertical clamp is used. It is important to identify the course of the renal vein and any venous anomalies on the preoperative CT scan to prevent inadvertently injuring these structures at this stage of the procedure. In the presence of a retroaortic renal vein or circum-aortic collar, the aortic neck should not be dissected circumferentially and vascular control should be obtained with a vertical clamp. The retroperitoneum over the aorta is then incised further caudally and the incision extended along the course of the right common iliac artery. The extent of the caudal dissection depends on the anatomic configuration of the aneurysm. If the aneurysm extends to the aortic bifurcation, it is sufficient to dissect only the common iliac arteries provided a suitable site for clamp application is identified. If the aneurysm extends to the distal common iliac arteries, both the internal and external iliac vessels should be dis-

sected free. This may be facilitated on the left side by mobilizing the sigmoid colon along its peritoneal reflection and reflecting it medially. The inferior mesenteric artery is then dissected free and vascular control obtained with a vessel loop. Patients are administered 100 units of intravenous heparin per kilogram, and the activated clotting time is confirmed to be twice the baseline value. Supplemental doses of heparin are administered throughout the procedure as dictated by the activated clotting time. Interestingly, a recent randomized controlled trial reported that heparin does not reduce thrombotic events or increase bleeding during aneurysm repair but is associated with a significant reduction in myocardial events.¹⁶⁴

During the time required for adequate mixing of the heparin, the availability of the necessary equipment is reviewed and confirmed with the operating room personnel. The appropriately sized prosthetic graft is selected. The graft diameter is sized according to the infrarenal aortic neck by visual inspection or with the calibrated graft rulers (i.e. “sizers”). The general “rule of thumb” is that the smaller graft should be selected when the aorta is between two graft sizes because the aorta always appears smaller after it is transected and redundant graft material at the proximal anastomosis is more difficult to correct than the opposite problem. A variety of vascular prostheses are available. Despite the contentions of the various manufacturers, there is no clear advantage for an individual graft and the choice should be determined by surgeon preference as dictated by ease of handling, cost, availability, and requirements for preclotting. The distal vascular clamps are applied to the external, internal, or common iliac vessels depending on the extent of the aneurysm and the character of the vessels. Occasionally, the iliac vessels are so calcified that they cannot be safely occluded with a clamp. Vascular control may be obtained intraluminally in this setting with the use of a balloon thromboembolism catheter after the aneurysm has been incised. The proximal aortic clamp is applied in sequence

after the distal clamps. The clamp is applied immediately below the renal arteries to facilitate an anastomosis to the proximal infrarenal aorta. The length of the infrarenal aorta should be sufficient to permit a safe anastomosis. However, a long infrarenal cuff should be avoided because it may become aneurysmal over time. Either a vertical or horizontal aortic clamp may be used, although the latter is preferred because it simplifies the anastomosis. The aorta is then incised longitudinally, and the incision is extended down the right common iliac artery as necessary. Attempts should be made to preserve the autonomic nerves overlying the distal aorta and proximal left common iliac artery in potent men. This can usually be achieved by incising the left common iliac artery transversely beyond the aneurysmal portion and tunneling the limb of the graft through the residual shell. The intraluminal thrombus and debris are removed from within the aorta, and all back-bleeding from the lumbar arteries is controlled with suture ligatures. The atheromatous debris within the aorta has been reported to be culture positive in approximately 25% of cases, although this has not been associated with long-term graft infections.^{165,166} The infrarenal aorta at the level of the planned proximal anastomosis may be completely transected, or the back wall may be left intact. Completely transecting the aorta makes the proximal anastomoses slightly easier, although leaving the back wall intact reinforces the anastomosis and provides the equivalent of an autogenous pledget. The proximal anastomosis is performed in an end-to-end configuration with a running 3–0 cardiovascular suture. All leaks in the suture line are repaired with similar 5–0 sutures and felt pledgets as necessary. The distal anastomosis or anastomoses are performed to the aortic bifurcation, common iliac arteries, or iliac bifurcation as dictated by the anatomy of the aneurysm. A 3–0 cardiovascular suture is used for anastomoses at the aortic bifurcation, and a similar 4–0 suture is used for the common iliac arteries. All anastomoses are flushed to remove any intraluminal debris before flow is restored. Blood flow is restored to the pelvis and lower extremities in sequence. Attempts should be made to flush initially into the internal iliac circulation to prevent embolization to the lower extremities. This can be facilitated by manually compressing the common femoral arteries for tube graft configurations. The lower torso should be reperfused gradually (i.e., one vessel at a time and one extremity at a time) to prevent hypotension and other acute sequelae associated with the reperfusion of the ischemic tissues. This process requires significant communication and coordination between the surgical and anesthetic teams. It is imperative that the patient is resuscitated prior to reperfusion and it is frequently necessary to delay this process to allow the anesthesiologists to achieve this objective. Reperfusion of the ischemic tissue causes the release of acid, potassium, and a variety of inflammatory mediators into the systemic circulation, all of which are potentially detrimental.

The inferior mesenteric artery may be reimplanted into either the body of the graft or the left limb if it is patent. Seeger et al.¹⁶⁷ reported that routine reimplantation of the inferior mesenteric artery resulted in decreased rates of colonic infarction and death after aortic reconstruction. However, a more recent randomized controlled trial demonstrated no benefit in terms of morbidity or mortality, although the authors suggested it may be beneficial for older patients and those with increased blood loss.¹⁶⁸ The colon and lower extremities should be interrogated with the Doppler ultrasound after reperfusion, and the heparin reversed with intravenous protamine sulfate after confirmation of adequate signals. The protamine dose is estimated based on the effectiveness of protamine (1 mg of protamine per 100 units of heparin), the initial dose of heparin, the current activated clotting time, and the elapsed time from the administration of heparin. The protamine should be administered slowly to prevent any untoward hemodynamic events.¹⁶⁹ Notably, a recent randomized controlled trial reported that protamine effectively reverses the

heparin effect but provides no clinical benefit during peripheral vascular surgery, including aneurysm repair.¹⁷⁰ The shell of the aneurysm and the overlying retroperitoneum are both closed with absorbable suture to provide a biologic tissue layer between the graft and the viscera. The retractors are then removed, the viscera are returned to their anatomic positions, the nasogastric tube is confirmed to be in the antrum, and the abdominal wall fascia is closed with standard technique. Interestingly, patients undergoing aortic reconstruction for aneurysmal disease have been reported to have a higher incidence of abdominal wall hernias than those undergoing reconstruction for occlusive disease.^{171–173}

The configuration of the aortic reconstruction (aortoiliac, aortofemoral) depends on the extent of aneurysmal involvement and the degree of occlusive disease. Aneurysmal involvement of the common iliac vessels should be considered an extension of the aortic process and treated appropriately. Specifically, common iliac arteries larger than 2.0 cm should be considered aneurysmal and replaced. The entire common iliac artery must usually be replaced, although it is possible to replace only the proximal segment if the aneurysmal involvement is isolated. Conversely, common iliac arteries smaller than 2.0 cm have a relatively benign natural history and do not need to be replaced since only a small percentage become aneurysmal and require treatment.^{30,31} Despite the fact that a patient may be a candidate for an aortic tube graft, it is often easier to perform an aortobiiliac graft because the terminal aorta is often very calcified. Aortobifemoral bypass grafts should be reserved for the small subset of patients who truly have concomitant aneurysms and severe occlusive disease since the risks of wound complications and graft infections are significantly greater. Indeed, the risk for graft infections is less than 0.5% for aortobiiliac grafts but approximately 2% for aortobifemoral grafts.^{30,31,174} It is important to remember the original indication for the procedure and choose the appropriate aortic reconstruction (aortobiiliac bypass for aortoiliac aneurysm, aortobifemoral bypass for aortoiliac occlusive disease). Admittedly, there is a role for aortobifemoral reconstructions in patients with aneurysmal disease, and it is futile to attempt an aortobiiliac reconstruction in patients with severe external iliac artery disease.

The postoperative care after open repair is fairly routine and predictable for the majority of patients. Patients are transferred directly from the operating room to the intensive care unit, although selective use of the intensive care unit may be appropriate.¹⁷⁵ Most of the patients are extubated in the operating room or shortly after arrival in the intensive care unit. The intensive care unit length of stay is usually 1 to 2 days, and the median total length of stay is 8 days.²⁵ Patients are encouraged to get out of bed and begin ambulating in the early postoperative period (i.e., 24 to 48 hours). Preoperative prophylactic antibiotics are continued for a total of 24 hours. Nasogastric decompression is continued until bowel function returns. Oral feedings are initiated after removal of the nasogastric tube and advanced quickly to solids. Patients are discharged when they are ambulatory, can tolerate a regular diet, have normal bowel function, and are sufficiently able to care for themselves. A subset of people require transfer to a rehabilitation or an extended care facility. Patients are usually seen in the clinic 2 weeks after discharge and then at 6 months thereafter. Additional clinic appointments may be necessary as dictated by any ongoing medical problems. Patients are not allowed to drive until their incisional pain has resolved and they have stopped taking pain medications. Furthermore, patients are discouraged from lifting objects heavier than 10 lbs for the first 6 months to reduce the incidence of incisional hernias.

Complications and Outcome. Open repair of intact abdominal aortic aneurysms is associated with significant mortality and morbidity.^{25,176,177} The attendant mortality rates have been discussed extensively in the preceding sections entitled

Principles of Management and Choice of Open or Endovascular Repair. Briefly, the contemporary mortality rate across the country has consistently been less than 5%.^{56–58} The overall morbidity rate remains less clear, although the specific complications have been well defined. Huber et al.²⁵ reported that 33% of all patients undergoing repair of intact abdominal aortic aneurysms across the United States develop some type of complication as defined by the *International Classification of Diseases*, ninth revision (ICD-9) postoperative complication codes. Similarly, Hua et al.⁵⁷ reported from the National Surgical Quality Improvement Program Private Sector that the overall incidence of morbidity after open repair was 35%.

Intraoperative complications can result from injury to the intra-abdominal structures during dissection, although these technical complications are not specific to the aneurysm repair. The small bowel, colon, ureter, and major venous structures (inferior vena cava, iliac veins, left renal vein) are particularly susceptible. Iatrogenic bowel injury at the time of abdominal aortic aneurysm repair is particularly problematic due to the potential to infect the prosthetic graft. If the colon is injured before the aneurysm repair, the defect in the colon should be fixed and the aneurysm repair should be aborted. If the small bowel is injured before the aneurysm repair, the same course should likely be followed, although this decision requires a modicum of clinical judgment. The infectious concerns must be balanced by the fact that the small bowel contents are sterile, patients usually receive a preoperative bowel preparation, a second procedure will be required to repair the aneurysm, and there is a small risk of aneurysm rupture during the intervening delay. Injury to the bowel during or after implantation of the aortic graft should be treated with repair of the defect, extensive irrigation, and prolonged antibiotics. Admittedly, these approaches are very conservative and it is noteworthy that multiple clinical series have attested to the safety of simultaneous aortic and gastrointestinal/urologic procedures.^{178–181} The ureter is susceptible to injury at the point where it crosses over the iliac bifurcation. Injury can be avoided by a heightened awareness of this anatomic location and dissection in the tissue plane immediately on top of the common iliac vessels. Inadvertent venous injury can be associated with significant bleeding. This can usually be controlled by direct pressure using sponge sticks and suture repair. The left renal vein may be transected if necessary. It should be transected near its junction with the vena cava, and the gonadal, adrenal, and lumbar branches should be preserved to maintain venous outflow from the kidney. Although somewhat inelegant, division of the left renal vein does not appear to affect renal function after abdominal aortic aneurysm repair.¹⁸² Transecting the common iliac artery or infrarenal aorta may facilitate exposure of the common iliac or retroaortic renal veins, respectively.

Excessive intraoperative bleeding may be encountered occasionally. Routine elective aneurysm repairs are usually associated with moderate intraoperative blood loss with a mean transfusion requirement of 1 to 2 units of packed red blood cells. Excessive bleeding may be caused by either the surgical trauma or coagulopathy. Reversal of the heparin with protamine may help correct the coagulopathic bleeding. Patients with significant bleeding and platelet counts below 50,000/mL should receive a platelet transfusion, and it should be considered for coagulopathic bleeding and counts below 100,000/mL. Transfusions of fresh frozen plasma are indicated for both patients with significant bleeding in conjunction with prolonged coagulation studies (>1.5 times control value) and those with coagulopathic bleeding. Massive bleeding, defined as more than 100% of the blood volume, may induce a dilutional coagulopathy with prolongation of the coagulation studies. Additional blood products should be set up in the blood bank in the event of significant bleeding. This may require an additional blood bank specimen. Intraoperative autologous transfusion devices should also be considered if not already in use.

Ischemia of the lower extremities has been reported to occur approximately 3% of the time after open repair.¹⁷⁷ The causes are multiple and include distal embolization, thrombosis, clamp injury, and technical errors. The lumen of the aneurysm is frequently filled with both thrombus and atheromatous debris that may serve as a source for both macro- and microembolization. The macroemboli usually lodge at the bifurcations of the major vessels; the microemboli usually lodge in the digital vessels and, unfortunately, are not amenable to mechanical extraction. Thrombosis may result from inadequate heparinization, hypercoagulable conditions, or poor arterial runoff. The technical conduct of the operation outlined previously is designed to minimize the ischemic complications. The specific maneuvers include anticoagulation, selection of a suitable site for distal clamp application and anastomosis, intraluminal control of severely calcified vessels, flushing of the vessels before clamp removal, and sequential removal of the vascular clamps. Further intervention is mandatory if the lower extremities are found to be ischemic. Anastomotic defects should be corrected. This may simply require disassembling and redoing the anastomosis, but often requires relocating it further distal on the outflow artery. If no problems are identified at the distal anastomosis, the femoral vessels should be explored and an intraluminal thrombus removed with a balloon embolectomy catheter. A transverse arteriotomy may be created in the common femoral artery if it is anticipated that only a thrombectomy will be required; a longitudinal incision should be created if a bypass (inflow or outflow) procedure is anticipated. The transverse arteriotomy can simply be closed with interrupted sutures without narrowing the lumen in the event that an additional bypass procedure is not necessary, whereas the longitudinal arteriotomy requires a patch closure. A bypass from the aortic graft to the femoral vessels is required if adequate inflow cannot be restored with thrombectomy alone. The popliteal artery below the knee should be explored and a thrombectomy performed if the extremity is still ischemic. This may be facilitated by creating a longitudinal arteriotomy on the below-knee popliteal artery that extends to the tibioperoneal trunk. This allows the passage of the balloon embolectomy catheter into all three tibial vessels under direct vision. A below-knee popliteal or tibial artery bypass is required if adequate perfusion to the distal extremity is not restored after patch closure of the popliteal arteriotomy. Predictably, a complex lower extremity revascularization in conjunction with an aortic reconstruction is associated with a significant degree of morbidity and dramatically increases the mortality rate.¹⁸³ The decision to proceed with an infrainguinal bypass depends on the status of the extremity and requires some clinical judgment. Aborting the procedure and allowing for a period of observation and rewarming is appropriate when popliteal Doppler signals are detected and the foot is cool yet not severely ischemic. Reoperation and definitive treatment may be necessary in the early postoperative period unless marked improvement is noted.

Many of the systemic complications that follow open aneurysm repair are not surprising, given the magnitude of the operation and the age/comorbidities of the patients. Cardiac complications (ischemia, infarction, arrhythmias, congestive heart failure) occur in up to 25%^{176,177,184} and are the leading cause of death after open aneurysm repair in many series. Pulmonary complications (pneumonia, ventilator dependence greater than 48 hours, acute respiratory distress syndrome) are also quite common and approximately 10% of the patients require prolonged ventilation.^{176,177} Deterioration of renal function, defined by an increase in serum creatinine or blood urea nitrogen, occurs in approximately 5% of cases, although acute renal failure requiring dialysis is rare (i.e. $<1\%$).¹⁷⁷ The potential causes of renal insufficiency in the perioperative period are numerous and include contrast nephrotoxicity, hypovolemia, atheroembolization, and the inflammatory response from the lower torso ischemia/reperfusion injury.

Postoperative bleeding requiring reexploration, intra-abdominal abscess, and abdominal wound complications are all relatively infrequent complications and are associated with all major intra-abdominal procedures.

Ischemic colitis has been reported to occur in approximately 2% to 13% of cases after open aneurysm repair.^{185,186} The reported incidence depends on the diagnostic algorithm and modality (routine sigmoidoscopy vs. selective sigmoidoscopy) and is dramatically increased after ruptured aneurysm repair. Indeed, the incidence of colonic ischemia after ruptured aneurysm repair in patients undergoing routine colonoscopy is approximately 25% to 40%.^{185,187} Multivariate analysis of patients undergoing both open and endovascular repair demonstrated that the duration of the procedure and preoperative renal insufficiency were also predictors of colon ischemia.¹⁸⁶ The sigmoid colon is affected most frequently, although all the sections of the colon may be involved. The ischemia may result from inadequate resuscitation, disruption of collaterals, and/or failure to revascularize a hemodynamically significant inferior mesenteric artery. Patients usually present with bloody diarrhea in the early postoperative period. However, the diagnosis should be considered in the absence of bloody diarrhea in patients with thrombocytopenia, multiple organ dysfunction, increasing abdominal pain/peritonitis, and generalized “failure to thrive.” The diagnosis may be confirmed by endoscopy. Although sigmoidoscopy is used most frequently, a complete colonoscopy is likely optimal due to the potential involvement of the other colon segments. Treatment depends on the endoscopic findings and clinical setting. The endoscopic findings range from mucosal ischemia to transmural necrosis. Unfortunately, it is often difficult to differentiate diffuse mucosal ischemia from transmural necrosis. Patients with mucosal ischemia alone should be treated with bowel rest, broad-spectrum antibiotics, total parenteral nutrition, and serial endoscopic examinations. Many of these lesions resolve spontaneously without long-term sequelae, although colonic strictures may develop in a subset of patients. Patients with transmural colonic necrosis should undergo laparotomy with resection of the involved segment, a proximal diverting colostomy, and a distal Hartmann pouch. After laparotomy, they should be maintained on broad-spectrum antibiotics and parenteral nutrition. The reported mortality rate in patients with transmural necrosis may range up to 85%.^{185,186} Maintaining antegrade flow through the internal iliac vessels, routinely implanting the inferior mesenteric artery, and avoiding disruption of the colonic collateral circulation may reduce the incidence of this adverse outcome.

Several other gastrointestinal complications are common after standard infrarenal abdominal aortic aneurysm repair.¹⁸⁸ A postoperative ileus develops in essentially all patients, with bowel function usually returning within 3 to 5 days. An ileus may persist beyond this time period in a subset of patients, although no additional therapy is usually required. Nasogastric decompression should be continued, narcotics minimized, electrolytes normalized, and ambulation encouraged. Either calculous or acalculous cholecystitis may develop after aneurysm repair. The mortality rates reported historically for postoperative cholecystitis were significant¹⁸⁹ and served as the catalyst for simultaneous cholecystectomy and aneurysm repair. Although this approach has been found to be safe and not associated with an increased risk for graft infections, it is usually reserved for patients with small stones or evidence of chronic cholecystitis. Pancreatitis may develop after abdominal aortic aneurysm repair, although the incidence is surprisingly low in light of the obligatory manipulation of the pancreas during repair. The treatment of pancreatitis in this setting is conservative and includes bowel rest, parenteral nutrition, and serial imaging.

Sexual dysfunction is quite common after both open and endovascular aneurysm repair as noted earlier. Erectile and/or orgasmic dysfunction have been reported to occur in 5% to

18% of men undergoing aortoiliac reconstruction.¹⁹⁰ The responsible mechanisms include interruption of the pelvic perfusion and injury to the autonomic nerves that overlie the distal aorta/proximal common iliac arteries. Injury to these autonomic nerves disrupts the internal sphincter mechanism of the bladder and results in retrograde ejaculation. Care should be exercised during aneurysm repair to maintain pelvic perfusion and avoid nerve injury to prevent these untoward complications. It is imperative that these potential complications be discussed with patients preoperatively.

Paraplegia after open infrarenal abdominal aortic aneurysm repair occurs with an incidence of 0.25%.¹⁹¹ The potential mechanisms for this devastating complication include embolization, thrombosis of the spinal artery, and disruption of the spinal blood supply. Paraplegia after aneurysm repair is an irreversible injury. Maintaining adequate prograde pelvic perfusion through the internal iliac arteries may minimize this complication.

The long-term outcome after open repair is generally favorable. Long-term survival is improved after aneurysm repair, although it falls short of the age-matched controls with survival rates of approximately 90%, 65%, and 40% at 1, 5, and 10 years, respectively.^{2,5,192} Cardiovascular causes account for the leading cause of death.¹⁹³ This underscores the importance of long-term medical follow-up and the AHA/ACC Guidelines for preventing myocardial infarction and death.^{150,193} Prosthetic aortic grafts are associated with long-term complications with a reported incidence of approximately 10% to 15% at 15 years.^{117,194,195} Notably, bifurcated grafts are associated with a higher incidence of complications (13%) than tube grafts (5%).³⁰ The long-term graft-related complications include infection, aortoenteric fistula, thrombosis, and pseudoaneurysm formation. Additional aneurysms of a sufficient size to merit intervention develop in approximately 5% to 15% of patients in either the iliac vessels or the aorta above the prosthetic graft.^{30,31} It is recommended that patients undergo CT of the complete aorta and iliac vessels 3 to 5 years postoperatively to screen for graft complications and additional aneurysms.¹⁹⁶ Furthermore, patients with prosthetic aortic grafts should receive prophylactic antibiotics before undergoing invasive procedures, including colonoscopy and dental extractions.

Endovascular Repair of Intact Abdominal Aortic Aneurysms

Technique. The preoperative evaluation and preparation before endovascular abdominal aortic aneurysm repair are significantly more complicated than for the open approach. The various imaging studies must be reviewed before it can be determined whether the endovascular approach is even feasible. Appropriate measurements must be taken and the necessary devices/components selected. An operative plan must be generated including specific modifications of the standard approach to overcome the patient's anatomic limitations and, thereby, extend the feasibility of the technique. Indeed, “preoperative planning, preoperative planning, and preoperative planning” have facetiously been identified as the three most important components of a successful repair.

A variety of imaging techniques (i.e., CT, catheter-based arteriography) have been employed to determine the feasibility of an aneurysm for endovascular repair and select the appropriate devices/components. However, CT arteriography with 3D reconstructions has emerged as the optimal approach. It is important to emphasize that no imaging technique is perfect and, consequently, a certain degree of flexibility is necessary for the operative plan. Measurements obtained from the 3D CT tend to overestimate the actual renal artery–internal iliac artery length assumed by the graft when deployed in vivo. Similar sizing limitations are associated with the catheter-based

arteriography techniques, and these have been attributed to the course of the catheter, the presence of intraluminal thrombus, and the conformational changes in the aorta that result from the stiff guide wires and/or the device itself.

The various devices/components should be selected using the underlying principles that the main body of the device should sit as close to the orifices of the renal arteries as possible, while the iliac limbs should extend to the orifices of the internal iliac arteries. Furthermore, the manufacturers' recommendations for sizing and device selection should be followed. Grafts seated well below the orifices of the renal arteries have been associated with proximal migration,¹⁹⁷ while oversizing the graft diameter beyond that recommended has been associated with both graft migration and aneurysm reexpansion.¹⁹⁸ The endograft is sized according to the anatomic configuration of the aneurysm and adjacent arteries, and this must be performed in advance of the procedure to ensure that the appropriate devices are available. The diameter and length of the infrarenal cuff, aneurysm, and iliac vessels must be measured precisely. In addition, the distance from the lowest renal artery to the aortic bifurcation and both renal bifurcations needs to be determined. The diameter of the proximal graft is chosen to oversize the aortic cuff and iliac arteries by approximately 10% to 20%. Additional devices should be ordered for each case including two iliac limbs and an aortic extension cuff to allow for any discrepancy between the preoperative plan and the actual course of the graft *in vivo*. Each endograft procedure and device configuration is "custom fit" for an individual patient. Worksheets are available from the manufacturers to confirm the suitability of an aneurysm for endovascular repair and to aid in the selection of an appropriate device. Technical assistance is available from the various manufacturers to facilitate every step of the process from initial assessment to component selection to deployment. Furthermore, physicians are required to complete a training course consisting of sizing exercises and monitored deployments.

The choice of the specific endovascular device is contingent upon the anatomic constraints of the aneurysm, device-associated outcome, and surgeon preference. There are specific differences between the various grafts that lend themselves to different clinical scenarios. The specific considerations include neck diameter, neck length/angulation, renal-internal iliac artery distance, common iliac artery diameter, and access vessel diameter. For example, a graft with suprarenal fixation may be more suitable for a shorter neck, while a lower-profile system (i.e., smaller outer diameter of the delivery sheath) may be most appropriate for patients with smaller access vessels (i.e., common femoral and external iliac arteries). Despite the initial concerns about compromising renal function, suprarenal fixation has been consistently shown to be safe.^{139,199} Deployment of the various endografts is reasonably involved from a technical standpoint; thus, it is not particularly surprising that most surgeons elect to concentrate on one or two devices. The ease of deployment and the precision of the deployment with regard to the location of the renal artery orifices also contribute to surgeon preference.

The need for adjunctive procedures to facilitate the endovascular repair is usually determined by the preoperative imaging and should be factored into the overall plan. The major concerns include stenotic access vessels and the absence of a suitable common iliac artery landing zone due to aneurysmal enlargement. The remedial procedures for small access vessels or significant occlusive disease include serial dilation or a retroperitoneal prosthetic iliac conduit. Repeated attempts to pass the device's sheaths through a diseased native vessel should be avoided and can result in vessel rupture at the common iliac bifurcation. Aneurysmal degeneration of the common iliac artery can be overcome by seating the iliac limb in the external iliac artery. This necessitates either embolizing or bypassing the ipsilateral internal iliac artery. Alternatively, the iliac limb of the endograft can simply occlude the internal iliac

artery flush provided the iliac bifurcation is sufficiently tapered.²⁰⁰ Several reports have documented that accessory renal arteries may be covered at the time of the endograft with little clinical sequelae.

The intraoperative preparation for endovascular repair is similar to that for the open approach, although there are several significant differences. The appropriate imaging equipment is mandatory. Ideally, this would entail a complete endovascular suite with a fixed fluoroscopic unit, although a portable unit with the appropriate vascular software and an imaging table is adequate. General endotracheal anesthesia is likely the standard, although a variety of techniques have been employed including both regional and local anesthesia. Indeed, the endovascular approach is well suited for these less invasive alternatives, particularly considering the feasibility of a completely percutaneous approach. Intraoperative autologous transfusion devices and a nasogastric tube are unnecessary. It is currently quite rare to convert to an open repair at the time of the initial implantation despite the early experience that reported a rate of up to 5%.^{62,63,65,201} However, it should be emphasized that endovascular aneurysm repair is a surgical procedure and should be performed in an operating room with strict aseptic technique.

Although the technique for implanting the various endografts is somewhat specific to the individual device, the basic steps for deploying a "generic" modular bifurcated device using an open femoral artery exposure is illustrated (Fig. 100.10). Briefly, the common femoral arteries are exposed and an umbilical tape is wrapped circumferentially around the vessels at the level of the inguinal ligament to facilitate vascular control. A variety of femoral incisions are possible, although a 2- to 3-cm transverse incision along the caudal border of the inguinal ligament is ideal and has been associated with a low incidence of postoperative wound complications. Approximately 2 cm of the common femoral artery is dissected free. It is not usually necessary to dissect the superficial and profunda femoral branches. While the dissection is being performed, the various device components are prepared on the back table by the surgical technologist. A pursestring suture using a 5-0 cardiovascular suture can be placed on the anterior aspect of the common femoral artery and left untied until the completion of the procedure. The various catheters/sheaths may be introduced through the center of the pursestring, thereby facilitating a rapid/simple closure of the artery at the completion of the procedure. The common femoral artery on the side chosen to introduce the main body of the device (ipsilateral groin) is punctured using an angiographic needle, and a 0.035-inch standard working wire (e.g., Bentsen) is passed into the abdominal aorta using fluoroscopic guidance. A 5-French introducer sheath is advanced over the guide wire using a Seldinger technique and vessel entry is confirmed by manual contrast injection. The working wire is further advanced into the thoracic aorta and exchanged for a longer 0.035-inch stiffened guide wire (e.g., Meier) using a catheter. Attention is then directed to the contralateral groin and in a similar manner a guide wire is advanced into the aorta and an appropriate-sized introducer sheath is inserted over the guide wire into the body of the aneurysm at approximately the L3 vertebral space. An angiographic catheter is advanced to the L1 vertebral body through the contralateral sheath and the catheter connected to the power injector. The patient is then anticoagulated with heparin using a standard protocol (100 units/kg) and therapeutic anticoagulation (activated clotting time twice baseline) is maintained throughout the procedure. The main body delivery catheter is introduced over the stiff wire through the ipsilateral groin and the upper limit of the main body positioned between the L1-2 vertebral bodies. Devices that do not have an integral sheath as part of their delivery system require an 18- to 22-French sheath to be inserted prior to introduction of the actual delivery catheter. Radiopaque markers on the graft facilitate the positioning and orientation of the main body.

FIGURE 100.10. General steps involved in the endovascular repair of an abdominal aortic aneurysm. The common femoral arteries are exposed bilaterally and stiff wires are introduced into the thoracic aorta under fluoroscopic guidance. An appropriate-sized large-diameter introducer sheath is inserted over the stiff wire into the body of the aneurysm at approximately the L3 vertebral space on the side contralateral to the one chosen for the main device. **A:** The main body delivery catheter is introduced over the stiff wire through the ipsilateral groin and the upper limit of the main body positioned between the L1-2 vertebral bodies. An aortogram is obtained and the location of the renal arteries identified. The location of the renal arteries is marked on the imaging screen and the position of the main body finely adjusted. **B, C:** The main body is deployed exposing the opening of the contralateral docking limb. The contralateral docking limb is cannulated and a stiff wire advanced into the thoracic aorta. Deployment of the contralateral limb is started by obtaining a retrograde arteriogram through the contralateral sheath in the opposite oblique projection to identify the orifice of the internal iliac artery. **D-F:** The location of the orifice is marked on the imaging screen; the contralateral limb is then introduced over the stiff wire, appropriately positioned, and deployed. A compliant aortic occlusion balloon is advanced over the ipsilateral stiff wire and inflated in the region of the infrarenal neck to mold the proximal and distal attachment sites. (*continued*)

An aortogram is obtained and the location of the renal arteries identified. The fluoroscope should be adjusted to optimize visualization of the infrarenal neck. A 5- to 10-degree craniocaudal angulation is usually sufficient to account for the anterior angulation of the infrarenal neck caused by the natural lumbar lordosis of the spine and the posterior bulging of the aneurysm sac. However, the optimal angulation or orientation may be estimated based on the preoperative CT images. The location of the renal arteries is marked on the imaging screen and the position of the main body adjusted. The main body is now deployed exposing the opening of the contralateral docking limb. Using a combination of a hydrophilic wire and a curved catheter, the contralateral docking limb is cannulated. This can be challenging at

times and requires a modest degree of catheter skills. Various maneuvers including different fluoroscopic projections, different shaped catheters, and proper orientation of the contralateral docking limb prior to deployment of the main body device can facilitate this step. It is imperative to confirm that the cannulating guide wire is actually within the body of the main endograft. This can be rapidly performed by visualizing the guide wire in two orthogonal projections and confirming that the stents of the endograft can be seen on either side of the cannulating guide wire. Alternatively, an arteriogram can be performed using a catheter within the main body. The contralateral wire is advanced into the ascending thoracic aorta under fluoroscopic guidance and exchanged for a stiff wire using a catheter.

FIGURE 100.10. (Continued)

Deployment of the contralateral limb is started by obtaining a retrograde arteriogram through the contralateral sheath in the opposite oblique projection (e.g., right anterior oblique projection for left limb) to identify the orifice of the internal iliac artery. The location of the orifice is marked on the imaging screen and a marker catheter is used to measure the distance from the contralateral docking limb to confirm the preoperative measurements and device selection. The contralateral limb is then introduced over the stiff wire, appropriately positioned relative to the docking limb and the orifice of the internal iliac artery, and then deployed.

After deployment of all the devices, a compliant aortic occlusion balloon is advanced over the ipsilateral stiff wire and inflated in the region of the infrarenal neck to mold the proximal attachment sites. The aortic balloon is then withdrawn and gently expanded at the main body/iliac limb overlap zone and both distal iliac artery fixation sites. A completion arteriogram is then obtained using an angiographic catheter placed through one of the introducer sheaths (Fig. 100.11). The arteriogram should adequately evaluate the proximal–distal fixation sites, the graft–graft overlap zones, and the orifices of the renal–internal iliac arteries. Additionally, it should include a delayed phase to help identify any endoleaks. Problems identified on the completion study should be corrected if possible. The potential remedial procedures include balloon dilation or aortic/iliac extension cuffs.

All sheaths, catheters, and wires are removed after the completion of the arteriogram. The common femoral arteriotomy is closed using the pursestring suture, although additional interrupted sutures are frequently necessary. The heparin is reversed with protamine (1 unit protamine/100 units heparin) after adequate signals are detected at the feet by Doppler ultrasound. The groin wounds are closed in layers with a continuous suture and the final skin later is closed with a subcuticular technique.

The immediate postoperative course is fairly uneventful. Patients are transferred to the general care ward after recovery in the postanesthesia care unit. Patients are started on an

appropriate diet the evening of the procedure and encouraged to get out of bed. Plain radiographs of the abdomen (four views, optimized for metal) are obtained on the first postoperative day, and patients are discharged thereafter. Patients are seen in the outpatient clinic at 1 month with an abdominal/pelvic CT scan. It is important to note that mild fever and the

FIGURE 100.11. Completion arteriogram after an endovascular aneurysm repair is shown. The arrow marks the caudal extent of the stent graft. Note that the iliac limbs have been intentionally crossed to facilitate the cannulation of the contralateral gate.

FIGURE 100.12. Plain radiographs of an endovascular graft demonstrating (A) strut fracture and (B) modular disruption. (Reproduced with permission from Magennis R, Joekes E, Martin J, et al. Complications following endovascular abdominal aortic aneurysm repair. *BJR* 2002;75:700–707.)

finding of air around the graft on CT are common occurrences immediately after endograft repair and have not been associated with graft infection.²⁰²

It is imperative that patients are followed long term given the uncertainty associated with the endovascular repair and the need for remedial procedures. As noted previously, new endoleaks have been identified as late as 7 years postoperatively.²⁰³ A variety of protocols and imaging techniques have been described, although an abdominal/pelvic CT scan with contrast at 12 months and then yearly noncontrast studies seem reasonable in the absence of any identifiable problems and an aneurysm sac that is not increasing in size. Indeed, Sternbergh et al.²⁰⁴ reported from a multicenter trial that the absence of an endoleak at 1 and 12 months predicted favorable long-term outcome. More frequent imaging may be indicated if the aneurysm continues to grow or there is evidence of an endoleak. The surveillance CT scans should include non-contrast and biphasic contrast views with delayed images to help identify any late endoleaks.²⁰⁵ Although not part of all surveillance protocols, early plain radiographs are very helpful to identify structural changes/problems with the grafts (Fig. 100.12). Duplex ultrasound has been employed as a surveillance study, but its accuracy is dependent on the local expertise of the vascular laboratory.^{206–208}

Complications and Outcome. The overall mortality and complication rates after endovascular repair have been reviewed in the sections entitled Principles of Management and Choice of Open or Endovascular Repair. Briefly, the mortality rate in the recent randomized trials and national series is approximately less than 2%,^{58–60,66,66} the perioperative complication rate is less than 25%,^{57,117} the rupture risk is approximately 1% per year,^{117,124} and the incidence of remedial procedures is approximately 10% per year.¹²⁸ Many of the same complications that can occur after open repair can occur after endovascular repair. However, the relative incidence of the various complications is significantly different, and several complications inherent to the endovascular repair have been identified.

A variety of potential complications may arise during insertion of the delivery catheter or introducer sheath. Indeed,

access problems secondary to iliac stenoses and/or tortuosity are the most common procedure-related complication. The outer diameters of the delivery sheaths are device dependent, but can range up to 24 French. These correspond to an outer diameter of approximately 7 mm (1 French corresponds to the circular cross-sectional diameter of $1/\pi$ millimeter, e.g., 24 French = $24/3.14$ mm or 7.6 mm). A variety of techniques are available to correct or overcome the access vessel stenoses, and these should be factored into the preoperative plan. Excessive force during insertion of these large sheaths or delivery catheters can result in serious injury and perforation of the vessels. Predictably, this can lead to significant hemorrhage and hemodynamic changes. The diagnosis can be confirmed by arteriography and the bleeding controlled intraluminally using the device sheath or a balloon catheter. A variety of endovascular salvage techniques are possible in this setting, including deployment of either the main device or a covered stent over the disrupted artery. Indeed, nearly all major arterial disruptions, with the possible exception of the proximal aorta, may be treated using endovascular techniques and do not necessitate emergent laparotomy. Safe conduct of an endovascular aneurysm repair is predicated by sufficient knowledge of the various salvage techniques, the necessary catheter and guide wire skills to execute them, and a complement of ancillary equipment. However, the adage that “prevention is better than the cure” holds true and endovascular surgeons should maintain a low threshold for constructing a retroperitoneal iliac conduit. Dissection within the arterial wall of the iliac vessels or aorta may also result from misdirection or excessive force during cannulation of the vessels. It can usually be corrected by cannulating the “true” lumen and reestablishing its integrity by deploying a peripheral (uncovered) stent.

Graft deployment can be associated with mechanical problems related to the delivery system or inappropriate positioning. A host of mechanical problems have been described, and the list will likely expand with widespread application of the devices and the introduction of newer systems. Many of the mechanical problems are device specific and related to the actual sequence of events and manipulations required. Troubleshooting guidelines and specific recommendations are available from the

manufacturers. Deployment of the endovascular graft below the proximal target site on the infrarenal aorta may be corrected using an aortic extension cuff. Attempting to reposition the graft further proximally after deployment has not been successful and is not recommended. Deployment of the endovascular graft across the orifices of the renal arteries can potentially be corrected by displacing the graft caudally. A guide wire can be passed over the flow divider and out the contralateral groin. The entire graft can then be retracted caudally by pulling on the wires. Alternatively, a large balloon can be inflated above the flow divider and retracted. Extreme care must be exercised during these maneuvers to prevent complete dislodgement of the proximal main body from the neck. Deployment of the graft across part of the renal orifice can be corrected by placing a stent within the lumen of the renal artery and thereby displacing part of the main body caudally. Deployment of the endograft across the lumen of one internal iliac artery is usually tolerated provided the contralateral vessel is patent and relatively free of occlusive disease. Indeed, it is relatively common to embolize a single internal iliac artery in patients with common iliac artery aneurysms to facilitate fixation of the graft limb in the external iliac artery. Occlusion of both internal iliac arteries or occlusion of one vessel in the presence of contralateral disease may render the pelvis ischemic. Occasionally, one of the iliac limbs can be pushed cephalad using a sheath and its dilator. It should be emphasized that many of these remedial procedures are not manufacturer approved and should only be attempted by experienced endovascular surgeons. Due to the advanced age of many of these patients and their attendant comorbidities, open surgical conversion should be contemplated only as a last resort after the endovascular options have been exhausted, again emphasizing the need for advanced endovascular skills.

It is relatively common to see an endoleak on the completion arteriogram. Treatment is contingent upon the specific type of leak and its associated natural history, although the majority of these early endoleaks ultimately resolve.²⁰⁹ The type 1 (attachment site) and type 3 (fabric tear or module interface) endoleaks are particularly concerning and every reasonable attempt to correct these defects should be made. The aneurysm sac is presumably still exposed to systemic pressure in the presence of a type 1 or type 3 endoleak, and, therefore, the rupture risk likely approaches that associated with the untreated aneurysm. Both the type 1 and 3 endoleaks can potentially be corrected by repeat balloon angioplasty at the proximal/distal attachment sites or at the modular interface. If these measures are not successful, additional extension devices can be deployed. With the exception of large proximal type 1 endoleaks, it is reasonable to manage most perioperative endoleaks expectantly since many seal spontaneously after reversal of the anticoagulation or within the first 6 months. Furthermore, it should be kept in mind that the inability to obtain a satisfactory exclusion of the aneurysm at the time of endograft implantation does not mandate a surgical conversion at the same setting. Consideration should be given to completing the procedure, allowing for a brief recovery, and discussing potential options in an elective, outpatient setting with the patient and his or her family. The potential options at this point include referral to another center with more expertise, open surgical repair with removal of any or all implanted devices, or no further treatment if the patient is a poor surgical risk. Type 2 endoleaks (retrograde branch vessel related) have a relatively benign natural history and do not merit aggressive intervention unless the aneurysm continues to increase in size over time. Type 4 (trans-graft) endoleaks are self-limiting and do not merit treatment at all. They are identified as a diffuse contrast “blush” at the time of the completion arteriography. They represent a diagnosis of exclusion and mandate that the more worrisome type 1 endoleak be excluded.

The spectrum of immediate postoperative complications after endovascular aneurysm repair is comparable to that outlined for after open repair and will not be repeated. However,

the incidence of major, systemic complications after endovascular aneurysm repair is quite small. It is noteworthy that the incidence of both paraplegia and bowel ischemia are comparable after endovascular and open repair, although the mechanisms are different and likely due to atheroembolism.^{186,210,211} Indeed, diffuse embolization to the small bowel has been reported after endovascular repair and is almost uniformly fatal.²¹⁰

The long-term complications after endovascular repair include endoleak, structural failure, need for remedial procedures, need for open conversion, and rupture. These ongoing risks further emphasize the importance of conscientious life-long surveillance. All type 1 and 3 endoleaks identified during surveillance merit further evaluation and correction given their ongoing rupture risk. Device migration has been reported to cause type 1 endoleaks and has been associated with neck length, site of deployment below the renal arteries, and surgeon/center experience.¹⁹⁷ The treatment of these late-occurring type 1 and 3 leaks is identical to that for those occurring earlier and includes identification of the specific site and remediation with either balloon angioplasty or an additional endovascular device, although the latter is most common. Type 2 endoleaks merit intervention and treatment if the aneurysm continues to increase in diameter. Identification of the type 2 endoleak can be challenging and may require selective catheterization of the superior mesenteric or internal iliac arteries.²¹² A variety of approaches have been described to treat the type 2 endoleaks including coil embolization, laparoscopic ligation of the feeder vessels, and direct translumbar injection of the aneurysm sac with glue or other thrombotic agents.

Aneurysms that continue to increase in size after endovascular repair merit further intervention and may require open conversion due to their ongoing rupture risk. Continued aneurysm growth has been associated with the type of prosthesis and baseline size in addition to the presence of endoleak.¹³⁰ It should be emphasized that the goal of aneurysm repair is to prevent rupture/death from rupture and that endoleak and even sac enlargement are surrogate markers of potential late failure of the therapy. Indeed, even the clinical significance of an enlarging sac in the absence of a visible endoleak is controversial as long as a secure proximal and distal fixation of the endograft has been demonstrated. To confound the issue further, rupture of aneurysms without an endoleak or a change in sac diameter has also been reported, leading some to describe the phenomenon teleologically as endotension. A presumed endoleak that is not detected on a properly performed contrast CT scan is typically not identified on a catheter-based arteriogram. The proper diagnostic investigation of an endoleak should include interrogation of all the fixation sites and modular interfaces and selective injections of mesenteric and hypogastric arteries with sufficient contrast dose and proper acquisition techniques. It should be emphasized that open conversion and explant of the endovascular graft is technically more challenging than a de novo open repair and usually requires suprarenal or supraceliac aortic control. It is not always possible (or necessary) to remove the whole endovascular graft, particularly when the device has suprarenal fixation. It is possible to transect the endovascular graft near the usual site of the infrarenal aortic anastomosis and incorporate the fabric/stents of the graft into the anastomosis. Temporary distal vascular control can be achieved by clamping the limbs of the endovascular graft. The limbs of a bifurcated surgical graft may be anastomosed directly to the endograft limbs if they are securely attached to the iliac artery.

A variety of device-specific complications, including strut fracture, fabric tears, and buckling of the graft, have been identified, and the list will likely increase with the introduction of newer systems. These may present at any time throughout the postoperative period. An extensive discussion of all the potential device-related complications and their treatment is beyond the scope of this chapter. Disturbingly, regression of the aneurysm has been associated with significant conformational

changes in the endografts and has resulted in limb thrombosis and disruption of the distal attachment sites.²¹³ These adverse outcomes in the presence of decrease in the aneurysm size have been termed the “paradox of success.”

Repair of Ruptured Abdominal Aortic Aneurysms

Open Repair. The approach to the patient with a ruptured abdominal aortic aneurysm is similar to the elective one, although several points merit further comment. It is important to realize that operative repair is the only acceptable treatment and the only effective means to prevent further hemorrhage. The diagnosis should be made in an expeditious fashion and the appropriate treatment initiated. The endovascular approach appears to be associated with a lower mortality rate, but this remains to be further documented given the inherent bias in terms of patient selection and publication.^{71,72,74–76}

The patient should be taken emergently to the operating room once the diagnosis of a ruptured aneurysm has been made. Unnecessary delays to complete the preoperative evaluation should be avoided. Unfortunately, the diagnosis is not always made in a setting where an operating room is immediately available. Given this scenario, the patient should be transferred to a setting in which an operating room is available or the necessary resources should be mobilized. The decision to transfer or treat locally should be dictated by the ultimate time necessary to get the patient to the operating room and the institutional resources. The operating room and anesthesia personnel should be notified immediately upon diagnosis and instructed that the patient is en route. The necessary instrument trays should be opened, the room temperature in the operating room increased, adjunctive measures to maintain body temperature obtained, and the intraoperative autologous salvage device prepared. Notably, hypothermia has been shown to be a strong, independent predictor of mortality after ruptured aneurysm repair.²¹⁴ The blood bank should be notified and instructed to send 6 units of blood to the operating room. This should be type O negative or type specific if cross matched units are not available. Furthermore, the blood bank should be instructed to expedite the cross match of additional red blood cells, fresh frozen plasma, and platelets. The patient should be prepared and draped before intubation and the induction of anesthesia. Simultaneously, the surgeon and assistants should be prepared to make the incision at the time of induction. Patients with ruptured aneurysms frequently become hypotensive after the induction of anesthesia because of its vasodilator effect.

A midline incision should be made and supraceliac aortic control obtained. This is facilitated by bluntly dissecting the gastrohepatic ligament, the crus of the diaphragm, and the connective tissue enveloping the aorta. The latter may be somewhat tenacious and requires a moderate amount of force. Vascular control can be achieved manually by either occluding the aorta between the fingers and thumb or compressing it against the vertebral bodies. Definitive control should be obtained with an aortic clamp, which can be guided along the arm, hand, and digits. Care should be utilized during these maneuvers to prevent injury to the esophagus or the aorta itself. Inexperienced surgeons may mistake the esophagus for the aorta in hypotensive patients. The presence of a nasogastric tube or pulse may aid in differentiating the aorta from the esophagus. Aortic control can also be achieved through a variety of other means: thoracotomy with occlusion of the descending thoracic aorta, intraluminal control of the infrarenal aorta with a Foley balloon, supraceliac control via a retroperitoneal approach, and intraluminal control with an aortic balloon catheter inserted through the femoral arteries. The aortic surgeon should be familiar with these various techniques because they can be

helpful in certain clinical settings, but the midline approach with supraceliac control is recommended for most ruptured infrarenal aneurysms. After supraceliac aortic control has been obtained, the infrarenal aorta is dissected and vascular control is achieved below the level of the renal arteries. The hematoma from the ruptured aneurysm often facilitates the dissection by displacing the normal tissue planes. However, the normal tissues may be obscured, and care should be taken not to injure the venous structures, particularly the left renal vein. The supraceliac aortic clamp can be released after infrarenal control has been obtained, and flow can be restored to the visceral vessels. It is imperative that these various steps are coordinated with the anesthesia team, and it is recommended that the supraceliac clamp be left in position to facilitate reapplication if necessary. Distal vascular control can be achieved with either vascular clamps or intraluminal balloons, depending on the character of the iliac vessels.

Patients can be heparinized after proximal and distal vascular control has been obtained, provided that the patient is doing well and the case is proceeding expeditiously.²¹⁵ However, the decision to anticoagulate the patient is contingent on a variety of factors, including the quantity of blood lost, presence of coagulopathic bleeding, body temperature, and hemodynamic status. Anticoagulation potentially reduces thrombotic complications, but it exacerbates coagulopathic bleeding. Before completion of the distal anastomoses, thromboembolectomy catheters should be passed distally through the iliac vessels to remove any thrombus or debris. It is recommended that the inferior mesenteric artery be implanted (if patent) to reduce the risk of postoperative colonic ischemia. The heparin effect can be reversed with protamine after confirmation of distal lower extremity arterial signals. The administration of fresh frozen plasma, platelets, or both should be considered at this point if any evidence of coagulopathic bleeding is noted.

The postoperative course after repair of a ruptured aneurysm is predictably more complicated and protracted than the course after elective repair.^{216–220} Both the intensive care unit and total hospital length of stay are significantly increased. The mortality and complication rates are likewise significantly increased. As noted earlier, the mortality rate for patients with ruptured abdominal aortic aneurysms who make it to the operating room is approximately 50%.⁵ The spectrum of postoperative complications after repair of a ruptured aneurysm is essentially the same as after elective repair, although the incidences are increased. The incidence of bowel ischemia may be as high as 40% and routine colonoscopy may be indicated.¹⁸⁷ Abdominal compartment syndrome²²¹ and adrenal insufficiency²²² have been reported after ruptured aneurysm repair and merit consideration in patients who are not doing well. Notably, adrenal insufficiency was identified in almost 70% of patients with unexplained postoperative hypotension after ruptured aneurysm repair.²²² Predictably, long-term survival is decreased relative to patients undergoing elective repair,²⁰⁰ although the overall quality of life is comparable.²²³

Endovascular Repair. The endovascular approach has the potential to impact the operative mortality rate for ruptured abdominal aortic aneurysms. Although the worldwide experience is relatively small, the early outcomes are impressive, particularly given the significant mortality/morbidity associated with the open repair, which has remained relatively constant over the past few decades.⁶⁹ Despite the appeal of the endovascular approach, its application requires a defined protocol/approach consisting of an experienced endovascular surgeon, a committed team, an available operating room with the necessary imaging equipment, and an inventory of suitable devices. Furthermore, the patient must be an acceptable anatomic candidate. Several recent studies have estimated that approximately 20% to 50% of patients with ruptured aneurysms are anatomically suitable for endovascular repair using conventional devices, although this number may

increase with the introduction of newer devices and/or the extension beyond the manufacturers' instructions for use.^{199,224–226}

The endovascular approach for the treatment of ruptured abdominal aortic aneurysms can be briefly summarized and has recently been described by Lee et al.²²⁷ Patients with a presumed diagnosis of a ruptured abdominal aortic aneurysm who are hemodynamically stable, as defined by a systolic blood pressure greater than 80 mm Hg and normal mentation, should undergo a rapid CT arteriogram to determine their suitability. Notably, aggressive fluid resuscitation should be avoided during this period to avoid the theoretical risk of releasing the retroperitoneal tamponade. The anatomic criteria for endovascular repair include an acceptable neck anatomy (length ≥ 10 mm, diameter ≤ 32 mm) and adequate access vessels (≥ 7 mm diameter). The operative plan is generated and the appropriate devices selected based on the CT findings, and patients are taken directly to the operating room from the scanner. Oversizing of the aortic neck greater than or equal to 20% and encroachment on the orifices of the renal arteries with adjunctive stenting are both tolerated in an attempt to limit the necessary inventory and increase the proximal fixation zone, respectively. Access to the common femoral arteries is obtained using a percutaneous approach with direct exposure and repair delayed until the completion of the procedure. The remaining conduct of the procedures is essentially the same as described in the elective setting. It is not usually necessary to occlude the aorta with an intraluminal balloon, although one should be readily available in the event that the patients become hemodynamically unstable.^{228,229} It should be noted that the criteria for an acceptable result are somewhat less in this setting and persistent attempts to achieve a perfect radiographic result should be avoided. The ultimate goal is to prevent further hemorrhage and to allow the patient to be resuscitated. Further interventions including conversion to open repair may be necessary at a later date, but these can usually be performed in an elective fashion.

ADDITIONAL CONSIDERATIONS

Isolated Iliac Artery Aneurysms

Isolated iliac artery aneurysms are rare and have been reported to occur with an incidence ranging from 0.03% in autopsy series⁶ to 2.2% in single-institution series.²³⁰ The common iliac artery is involved in approximately 70% of the cases, and the internal iliac artery in the remainder.²³¹ Aneurysmal involvement of the external iliac artery, either in combination with the common iliac artery or alone, is distinctly rare. These isolated iliac artery aneurysms should be differentiated from the common iliac artery aneurysms that occur concomitantly with abdominal aortic aneurysms. Simultaneous aneurysmal involvement of the aorta and common iliac arteries occurs in about 10% to 20% of all abdominal aortic aneurysms^{6,7}; this pattern should be considered as one disease process and treated accordingly.

The natural history of isolated iliac artery aneurysms is poorly defined because of their low incidence. The clinical risk factors appear to be similar to those for abdominal aortic aneurysms with the highest incidence seen among elderly men. Unlike patients with abdominal aortic aneurysms, a significant proportion of patients with isolated iliac artery aneurysms present with symptoms.²³¹ These symptoms may result from either rupture or compression of adjacent structures including the bowel, ureters, iliac veins, and nerves. The clinical presentation of patients with a ruptured iliac artery aneurysm is similar to that of ruptured abdominal aortic aneurysms, and the diagnosis should be included in the differential for patients with genitourinary symptoms and normal findings on urinalysis and testicular examination. CT arteriography is optimal for

confirming the diagnosis of an isolated iliac artery aneurysm. The utility of ultrasonography is limited by the posterior course of the iliac vessels and the overlying bowel. Large iliac artery aneurysms may occasionally be palpated during rectal or gynecologic examination, and ruptured iliac artery aneurysms may present with ecchymosis of the perineum.

The principles of treatment for asymptomatic, isolated iliac artery aneurysms are similar to those for abdominal aortic aneurysms, and operative repair is justified when the risk for rupture offsets the risk of repair. Unfortunately, the natural history of isolated iliac artery aneurysms and the appropriate threshold for repair remain unresolved. The reported growth rate for iliac artery aneurysms less than 3 cm is 0.11 cm/y, while that for aneurysms 3 to 5 cm is 0.26 cm/y.²³² Although rupture has been reported for aneurysms smaller than 2 cm, it is rare for aneurysms smaller than 3 cm to rupture.^{230,233} Operative repair is generally recommended for good-risk patients with isolated iliac artery aneurysms greater than or equal to 3.5 cm. The frequency of surveillance imaging studies should be dictated by the size of the aneurysm, with yearly studies appropriate for aneurysms less than 3 cm and 6-month intervals appropriate for aneurysms between 3 and 3.5 cm.²³⁰

The treatment or repair of isolated iliac artery aneurysms depends on the specific vessel involved and the extent of the aneurysm. Theoretically, common iliac artery aneurysms can be repaired with an interposition graft or a covered stent provided that there is a sufficient proximal and/or distal neck to sew the anastomosis or seat the graft. However, this is rarely an option because the aneurysmal involvement of the vessel usually extends over its whole length. Therefore, repair necessitates replacing the whole common iliac artery with a bifurcated graft similar to the approach for patients with combined aortic and iliac artery aneurysms. Both open and endovascular approaches are available and the concerns about the individual choice (i.e., open vs. endovascular) are likely similar to that outlined for abdominal aortic aneurysms. Additionally, the principles of treatment for both the open and endovascular approach of isolated iliac artery aneurysms are similar to abdominal aortic aneurysms. In the case of open repair, the proximal anastomosis should be performed immediately below the renal arteries to prevent subsequent aneurysmal degeneration of the infrarenal cuff, while the distal anastomosis should be performed at the common iliac bifurcation on the involved side. The distal anastomosis on the uninvolved common iliac artery can be performed to a nonaneurysmal segment. For the endovascular repair, the graft should be seated immediately below the renal arteries and at the takeoff of the internal iliac artery on the side opposite the aneurysm. The iliac limb on the side of the aneurysm is seated in the external iliac artery and necessitates embolization or bypass of the ipsilateral internal iliac artery.

The treatment of internal iliac artery aneurysms is exclusion. This can be performed using either an endovascular or open approach, although the former is likely preferred due to its simplicity. Bypass of an internal iliac artery aneurysm is not usually possible because there is rarely a proximal or distal neck. Indeed, the aneurysmal involvement usually extends to the common iliac bifurcation and the distal aspect usually arborizes into multiple smaller vessels. The principles of the endovascular treatment include obliterating both the arterial inflow and the outflow of the aneurysm. The outflow is usually thrombosed using selective coil embolization, although a variety of other agents have been described. Placing a covered stent across its orifice extending from the common to the external iliac vessels eliminates the inflow. The open approach requires vascular control of the distal common iliac and proximal external iliac arteries. The internal iliac artery is then opened by incising the aneurysm, and the branches are oversewn from within. The proximal internal iliac artery can be either oversewn at its take-off or the resultant defect at the common iliac bifurcation can be repaired with patch angioplasty. The appropriate treatment

for patients with bilateral internal iliac arteries remains unclear. Exclusion of both vessels has the potential to cause severe pelvic ischemia that may not be remediable. A conservative approach is likely justified in this setting with a higher threshold for intervention appropriate for the second vessel. Treatment options include excluding only the larger vessel, attempted revascularization, and staged exclusion after sufficient time has elapsed to facilitate potential collateral development. Regardless of the treatment option, it is important to assess the status of the pelvic circulation including the profunda femoral artery.

Inflammatory Abdominal Aortic Aneurysms

Approximately 5% of all abdominal aortic aneurysms are described or considered inflammatory.²³⁴ These are characterized by a dense inflammatory response encasing the anterior and lateral walls of the infrarenal aorta with sparing of the posterior aspect. The inflammatory response consists of a dense cellular infiltrate that has a white, glistening appearance on inspection. The inflammation results in an increase in wall thickness with the difference between the inner and outer diameters of the aorta ranging from 1 to 5 cm. The cause of this inflammatory process remains unresolved, but it is likely an autoimmune phenomenon. Indeed, some type of autoimmune disorder has been identified in up to 20% of patients with inflammatory aneurysms.²³⁵

Patients with an inflammatory abdominal aneurysm are predominantly male and frequently present with symptoms of back or abdominal pain. The triad of a pulsatile abdominal aortic mass, abdominal pain, and an elevated sedimentation rate has been described. Abdominal ultrasonography or CT may confirm the diagnosis. The anterior and lateral aspects of the aortic wall are thickened and hypoechoic on the sonogram. The CT findings are characteristic and include a thick, contrast-enhancing wall in the distribution described. An inexperienced observer may confuse the CT findings with those of a ruptured abdominal aortic aneurysm. Hydronephrosis with medial displacement of the ureters is frequently seen in contradistinction to the lateral displacement seen with noninflammatory aneurysms. Indeed, this entity may share some pathogenetic pathways with retroperitoneal fibrosis.

The treatment of inflammatory abdominal aortic aneurysms is essentially the same as that for the more common, noninflammatory variety. Nonoperative treatment with corticosteroids has been advocated in the past, although this approach is likely ineffective and has largely been abandoned.²³⁶ It has been suggested that the rupture risk of inflammatory aneurysms is less than that for the noninflammatory variety because the wall thickness is increased. However, this is not true, and patients should not be lulled into a false sense of security. It should be emphasized that most aneurysms rupture through their posterior or posterolateral aspect, which is not involved in the inflammatory process. The open repair of an inflammatory abdominal aortic aneurysm is complicated by the fact that the adjacent structures, including the duodenum, colon, and ureters, may be involved in the process and densely adherent to the aortic wall. The operative blood loss and procedure time associated with the open repair of inflammatory abdominal aortic aneurysms may be greater than the more common, uninvolved type. These potential technical difficulties should be factored into the operative indications and size-related threshold for the open approach.

The endovascular approach may be the optimal treatment for patients with inflammatory abdominal aortic aneurysms due to the concerns about the inflammatory process and adherent structures outlined previously.^{237–240} Notably, Puchner et al.²⁴⁰ performed a meta-analysis of patients undergoing endovascular repair for inflammatory aneurysms and reported that the inflammatory process resolved in approximately 50% of the cases. The technical difficulties associated with the open repair

can be reduced by using the retroperitoneal approach. Inflammatory aneurysms can be repaired through a transperitoneal approach, and this scenario occasionally arises when the diagnosis is not suspected preoperatively. Regardless of the open approach, no attempt should be made to mobilize the adherent structures, specifically the duodenum, because of the potential for accidental injury. Proximal aortic control can be achieved either immediately above the renal arteries or above the visceral vessels. Alternatively, intraluminal aortic control can be achieved with a balloon catheter, although this approach is less appealing. Distal control can usually be achieved at the common iliac arteries or at the level of their bifurcation. The duodenum and other adherent structures should be mobilized by incising the wall of the aneurysm and then reflecting them laterally. The proximal anastomosis can usually be performed to the infrarenal aorta after the aneurysm wall has been incised. The preoperative placement of ureteral catheters may facilitate their identification intraoperatively and can be helpful in patients with hydronephrosis. An increased incidence of anastomotic pseudoaneurysms has been demonstrated in patients with inflammatory aneurysms after open repair and likely justifies long-term surveillance.^{241,242}

Juxtarenal and Suprarenal Abdominal Aortic Aneurysms

The management of aneurysms extending to the level of the renal arteries or more cephalad is complicated, and, predictably, the morbidity and mortality rates associated with open repair are increased.^{243–245} Interestingly, several recent reports from centers of excellence have documented mortality rates comparable to those reported for infrarenal repairs, although it is unlikely that these findings are applicable nationwide.^{246–248} Repair of these complex aneurysms is complicated by the obligatory period of renal and visceral ischemia associated with aortic occlusion during the proximal anastomosis. Indeed, the renal complication rates range from 15% to 20% even from these select centers of excellence.^{246–248} These increased morbidity and mortality rates should be factored into the decision algorithm and threshold for operative repair. Elective operative repair is usually recommended for patients with aneurysms 6 cm or larger in diameter in this setting, although the 5.5-cm criterion may be appropriate for very good-risk patients and those with juxtarenal aneurysms who will require only a short period of suprarenal aortic occlusion.

Abdominal aortic aneurysms extending to the renal arteries or more cephalad may be repaired via either a retroperitoneal or a transperitoneal approach, although the former is optimal. The *retroperitoneal* approach, with elevation of the left kidney, obviates the concerns about the left renal vein and simplifies exposure of the abdominal aorta. Furthermore, the distal descending thoracic aorta may be exposed by incising the diaphragm and its crus. Admittedly, it is more difficult to expose the right renal and common iliac arteries. The proximal anastomosis may be fashioned as a large hood incorporating the orifices of the renal and visceral arteries. Separate revascularization of the left renal artery is occasionally necessary if the orifices of the renal arteries are splayed too far apart by the aneurysm. The *transperitoneal* repair requires exposing the suprarenal aorta for clamp application. This is facilitated by retracting the left renal vein inferiorly after ligating its adrenal, gonadal, and lumbar branches. As noted earlier, the left renal vein may be ligated near its confluence with the cava without adverse sequelae.¹⁸² However, the named collaterals of the left renal vein (e.g., adrenal) should be preserved with this approach. The anterior surface of the aorta at the level of the visceral vessels is encased by dense neural tissue that can be incised. Incising the crus of the diaphragm that envelops the

lateral aspect of the aorta further facilitates clamp application. The configuration of the proximal anastomosis in the setting of the transperitoneal approach depends on the extent of the aneurysm and the vessels involved. Juxtarenal aneurysms can be repaired by obtaining suprarenal control and sewing the proximal anastomosis at the level of the renal orifices. The proximal anastomosis for suprarenal aneurysms can be performed by fashioning an anastomotic hood that incorporates most of the visceral vessels, although this frequently requires separate revascularization of one renal artery.

Endovascular aneurysm repair has been reported to be feasible for juxtarenal and suprarenal abdominal aortic aneurysms.^{249–252} The approach is based on constructing a suitable landing zone for the more traditional endograft in patients with an inadequate or short infrarenal neck. This is accomplished using an individually designed fenestrated endograft that contains orifices that correspond to the renal and visceral vessel. These fenestrations permit the introduction of individual covered stents. Although the worldwide experience is somewhat limited and the devices are not commercially available in the United States, the technique has been shown to be feasible and safe and to prevent aneurysm rupture in the short term.^{249–252} The technique likely represents the proverbial “next frontier” for endovascular aneurysm and may dramatically impact the care of another group of complex patients not amenable to open repair.

Combined endovascular and open (i.e., “hybrid”) approaches have also been used to treat the juxtarenal and more complex proximal aneurysms. These techniques, somewhat similar to the fenestrated graft approach, are based on constructing a suitable aortic neck to land a traditional endograft by “debranching” the renal or visceral vessels. For example, a suitable landing zone below the superior mesenteric artery could be created for a juxtarenal aneurysm by performing bilateral iliorenal bypasses. Although theoretically appealing, early reports have demonstrated that the mortality rates for the hybrid approach for complex aneurysms have been comparable to open repair.^{253,254} Indeed, the magnitude of the revascularization procedure appears to be comparable to that of the more traditional open repair and, accordingly, the approach does not appear to extend the indications for aneurysm repair to older, sicker patients.

Infected Abdominal Aortic Aneurysms

Infected abdominal aortic aneurysms comprise a small subset of all abdominal aortic aneurysms, accounting for less than 1% of all repairs.²⁵⁵ The term *mycotic aneurysm* has traditionally been used to refer to infected aneurysms, although it is a misnomer that has led to a significant amount of confusion. A newer classification system, proposed to clarify the situation, consists of four groups based on the underlying mechanism: (a) mycotic aneurysm, in which a septic embolus from the heart infects an artery; (b) microbial arteritis, in which bacteria infects an atherosclerotic but nonaneurysmal artery and cause aneurysmal degeneration; (c) existing aneurysms that become infected; (d) traumatic pseudoaneurysm with concomitant bacterial inoculation.²⁵⁶ Microbial arteritis resulting from hematogenous bacterial spread currently accounts for approximately 80% of all cases of infected aortic aneurysms.^{257,258} *Salmonella* causes approximately 40% of all aneurysmal infections in contemporary series with the remainder caused by *Streptococcus*, *Staphylococcus*, *Bacteroides*, *Arizona hinshawii*, *Escherichia coli*, and *Pseudomonas aeruginosa*.²⁵⁶

The diagnosis of infected aortic aneurysm is often difficult and the clinical presentation insidious. Patients may present with fever, back/abdominal pain, or both. The physical examination is often remarkable for a palpable abdominal mass and the presence of peripheral emboli. Laboratory studies are notable for an elevated leukocyte count and positive blood

cultures, although the latter are present only 50% of the time^{258,259} and negative blood cultures do not exclude the diagnosis. CT is the most useful diagnostic study, and the features suggestive of an infected aneurysm include a periaortic mass, an aneurysm in an atypical location, periaortic fluid or gas, retroperitoneal inflammation, and frank rupture. The angiographic finding of a saccular or eccentric aneurysm in an atypical location is also suggestive of an infected aneurysm.

The treatment of an infected aneurysm requires control of hemorrhage in the presence of rupture, removal of all infected tissues, and restoration of perfusion to the viscera and lower torso. Indeed, these treatment concerns and the management options are identical to those for patients with infected aortic grafts, a far more common problem. Patients should be started on broad-spectrum antibiotics when the diagnosis is suspected, although antibiotic therapy alone is not sufficient and the operative intervention should not be delayed in an attempt to sterilize the retroperitoneum. Patients with suspected rupture should undergo emergent exploration through either a transperitoneal or retroperitoneal approach. After vascular control has been obtained, the retroperitoneum should be explored, and intraoperative cultures with an immediate Gram stain should be obtained. Several options for arterial reconstruction are available, including in situ replacement with a prosthetic or cadaveric graft, ligation of the infrarenal aorta with extra-anatomic bypass (axillofemoral, femorofemoral configuration), or in situ replacement with staged extra-anatomic bypass and subsequent removal of the in situ graft. The choice is contingent on the character of the aorta, degree of inflammation in the retroperitoneum, suspected organism, and hemodynamic status. In situ replacement of the infected aneurysm with a prosthetic or cadaveric graft is a reasonable option if retroperitoneal inflammation is minimal and the Gram stain is negative. Ligation of the infrarenal aorta with extra-anatomic bypass at the same session is the recommended approach in most settings, although this is a major undertaking. The three-stage approach of in situ replacement followed by extra-anatomic bypass and graft explant is reserved for patients who cannot tolerate the simultaneous procedure because of underlying comorbidities or hemodynamic instability. The integrity of the aortic stump at the time of ligation and the potential for dehiscence or breakdown of the suture line are major concerns. The aorta should be débrided back to grossly uninvolved tissue and sutured in two layers with a running horizontal mattress and a simple continuous technique using nonabsorbable monofilament suture. A pedicle of omentum can be mobilized and approximated next to the aortic stump to help control the retroperitoneal inflammation and minimize the risk for stump dehiscence. When the diagnosis is suspected preoperatively and no evidence of rupture is found, the staged approach with extra-anatomic bypass followed by graft removal is recommended. The procedures are usually performed 2 to 3 days apart to allow the patients a period of recovery. Patients should be anticoagulated between procedures to prevent thrombosis of the extra-anatomic bypass resulting from competitive flow. Fortunately, the risk of graft thrombosis and graft infection during the intervening period is small. Endovascular repair of infected aortic aneurysm has been reported and should be considered an additional alternative.²⁶⁰ Although the long-term safety of the endovascular approach remains unclear in this setting, it may serve as a temporizing approach that converts an urgent problem to an elective one. A recent meta-analysis by Kan et al.²⁶¹ reported that the endovascular approach was reasonable, but the incidence of subsequent endograft infection was significant in patients with ruptured aneurysms and those with fevers. They concluded that endovascular repair could be used as a bridge in this setting (i.e., ruptured aneurysm, febrile) prior to definitive open repair. Mycotic aneurysms involving the suprarenal aorta pose a particularly challenging problem, but fortunately they are uncommon. In situ replacement with a prosthetic or

cadaveric graft is frequently the only available option. Extra-anatomic bypass (hepatorenal and splenorenal) of the renal arteries with ligation of the suprarenal aorta is an option but represents a significant undertaking and should be reserved for select cases.

Patients with infected aneurysms, regardless of the arterial reconstruction, require long-term antibiotics and follow-up. Patients should receive intravenous antibiotics for 6 weeks, with the specific choice depending on the culture results. After completing the intravenous antibiotics, patients should be started on oral antibiotics, although the duration of treatment remains unresolved. Patients should be treated with at least 6 months of oral antibiotics and suppressive, lifelong therapy may be appropriate. Additionally, patients should undergo serial CT scans to assess the retroperitoneum and the status of the in situ graft when applicable. A CT scan is usually performed at 2 weeks, 3 months, and 6 months, and then at 6-month intervals thereafter. This is not necessary for patients with extra-anatomic revascularization in the absence of retroperitoneal inflammation. Predictably, the morbidity and mortality rates associated with infected abdominal aortic aneurysms are significant, with a 40% mortality rate reported in a recent publication.²⁶²

Aortoenteric Fistulas

An aortoenteric fistula is a communication between the aorta and the bowel. The duodenum is involved most commonly at the site where it crosses over the aorta, but the communication can develop between almost any portion of the intestine. Primary aortic fistulas result when nonspecific abdominal aortic aneurysms erode into the bowel and are distinctly rare, with a reported incidence of 0.04% to 0.07% in autopsy series.²⁶³ Debonnaire et al.²⁶⁴ identified 18 primary aortoenteric fistulas through a survey of 196 Belgian surgeons and reported a mortality rate of 30%. Secondary aortic fistulas result from the erosion of a prosthetic aortic graft into the bowel; they are significantly more common, with a reported incidence of 0.1% to 2.0% after aortic reconstruction.²⁶⁵ Notably, they can occur after endovascular aneurysm repair.²⁶⁶ The management of both primary and secondary aortic fistulas is the same.

The diagnosis of an aortoenteric fistula is often difficult and mandates a high index of suspicion. Patients usually present with gastrointestinal bleeding manifested as either hematemesis or melena. The initial episode of gastrointestinal bleeding is often self-limited and has been described as a “herald” bleed. The diagnosis of aortoenteric fistula should be foremost among the differential when a patient with a known aneurysm or prior aortic reconstruction presents with intestinal bleeding. Patients should undergo endoscopic evaluation of the upper and lower intestinal tract to determine the source of bleeding. It is imperative that the clinical suspicion of an aortoenteric fistula be communicated to the endoscopist to ensure that the third and fourth portions of the duodenum are adequately examined. This occasionally requires the use of a pediatric colonoscope. The endoscopic findings of erosion, thrombus, active bleeding, or visible prosthetic graft in the third or fourth portion of the duodenum are diagnostic of an aortoenteric fistula and mandate emergent laparotomy. Mild duodenitis and gastritis are frequently seen at the time of endoscopy and do not exclude the diagnosis of an aortoenteric fistula. Notably, the findings during upper endoscopy are normal in up to 30% of patients with a documented aortoenteric fistula.²⁶⁷ A CT should be performed if the results of endoscopy are inconclusive. The findings on CT that suggest an aortoenteric fistula include inflammation within the retroperitoneum, an anastomotic pseudoaneurysm, close approximation of the bowel and the prosthetic aortic graft or aneurysm, and loss of the normal tissue planes between the third portion of the duodenum and

the aorta or prosthetic graft. Occasionally, both endoscopy and CT are nondiagnostic despite the clinical suspicion of an aortoenteric fistula. Exploratory laparotomy is recommended in this setting for both diagnosis and treatment. Adherence of the bowel to the aorta at the time of the initial exploration suggests an aortoenteric fistula and mandates obtaining suitable proximal and distal control of the aorta, iliac vessels, or prosthetic graft before further dissection. The diagnosis cannot be excluded until the bowel is entirely separated from the retroperitoneum.

The treatment of an aortoenteric fistula requires repair of the defect in the gastrointestinal tract in addition to repair of the aneurysm or treatment of the infected prosthetic graft. Treatment of the gastrointestinal defect is usually straightforward and is based on standard surgical principles.²⁶⁸ After the fistula is disassembled, the edges of the bowel can be débrided and a primary closure performed with either a stapler or sutures. A limited bowel resection or diversion of the enteral tract may be necessary. The intraoperative and longer-term management of the aortic aneurysm or prosthetic graft is the same as that outlined earlier for infected aortic aneurysms. Indeed, aortoenteric fistulas represent a variant of infected aortic aneurysms. In situ replacement of the prosthetic graft or infrarenal aorta, ligation of the infrarenal aorta with excision of the prosthetic graft and extra-anatomic bypass, and in situ replacement with staged extra-anatomic bypass and subsequent graft excision are all reasonable options. The clinical scenario usually dictates the choice. Ligation of the infrarenal aorta with excision of the graft and extra-anatomic bypass is recommended in most cases. However, in situ repair is appropriate for patients who are older or sicker, those with minimal retroperitoneal inflammation or evidence of hemodynamic instability, and those in whom ligation of the infrarenal aorta would compromise the renal arteries. Additionally, patients should be maintained on long-term antibiotics and undergo serial imaging studies, as outlined for infected aneurysms.

Venous Anomalies

Anomalies of the vena cava and renal veins are occasionally encountered at the time of aortic reconstruction. The common anomalies are related to the embryologic development of the iliac veins and vena cava. The four most clinically relevant anomalies include duplication of the inferior vena cava (0.2% to 3.0%), left-sided vena cava (0.2% to 0.5%), circumaortic left renal vein (1.5% to 8.7%), and retroaortic renal vein (1.2% to 2.4%).²⁶⁹ Patients with a duplicated inferior vena cava have large veins that run parallel to the infrarenal aorta and join together either anterior or posterior to the aorta at the level of the renal vein. In the case of a left-sided inferior vena cava, a large vein runs parallel to the left side of the aorta, and the traditional right-sided vena cava is absent. The left-sided vena cava crosses the aorta at the level of the renal vein to become the suprarenal inferior vena cava. The gonadal and adrenal veins on the right drain directly into the renal vein in a mirror image of the normal anatomy. The circumaortic left renal vein forms a collar of veins that surrounds the aorta at the normal level. In the case of a retroaortic left renal vein, a single vein runs posterior to the aorta at a slightly more caudal location. Notably, both duplication of the inferior vena cava and left-sided vena cava can be associated with other venous anomalies, including a circumaortic or retroaortic renal vein.

The diagnosis of the various venous anomalies can usually be made preoperatively on CT. Identification of the vena cava and left renal vein should be part of the mental checklist used when the preoperative CT scans are reviewed. The various anomalies may not become evident immediately in the operating room if missed on the preoperative imaging studies. A very prominent left renal vein at the usual location or slightly inferior

is suggestive of a left-sided vena cava, whereas the absence of a left renal vein despite dissection along the anterior aspect of the aorta at the level of the superior mesenteric artery is suggestive of a retroaortic renal vein.

The open repair of an infrarenal abdominal aortic aneurysm in a patient with a venous anomaly is essentially the same as the standard approach, although additional care should be exercised to prevent inadvertent injury. Exposure of the infrarenal neck is more difficult in the presence of a duplicated or left-sided vena cava. However, sufficient exposure can usually be obtained by gentle dissection and mobilization of the venous structures. The presence of a duplicated or left-sided vena cava is a relative contraindication to the left retroperitoneal approach. A circumaaortic left renal collar or retroaortic left renal vein presents a potential hazard when the proximal aortic clamp is applied. A vertical aortic clamp is recommended and obviates the dissection on the posterior aspect of the aorta. Transecting the aorta may facilitate exposure of a retroaortic renal vein when significant bleeding is encountered.

Renal Anomalies

Congenital variations in the renal anatomy may complicate the repair of an abdominal aortic aneurysm. Specifically, their presence may complicate the dissection during open repair because they are frequently associated with multiple renal arteries, aberrant venous return, and abnormally positioned ureters. The various congenital anomalies of the upper urinary system have been classified in an attempt to standardize the approach for vascular surgeons.²⁷⁰ The anomalies have been broken down into abnormalities of position, including simple ectopia, and abnormalities of both form and fusion, including horseshoe kidney, crossed renal ectopia without fusion, and crossed renal ectopia with fusion. An ectopic kidney may be positioned anywhere from the pelvis to the thorax. Common forms of ectopic kidney include the pelvic kidney, located opposite the sacrum and below the aortic bifurcation; the lumbar kidney, located opposite the sacral promontory in the iliac fossa and anterior to the iliac vessels; the abdominal kidney, located above the iliac crest adjacent to the second lumbar vertebra; and the thoracic kidney, which can be located above the diaphragm in the posterior mediastinum. In a horseshoe kidney, two distinct renal masses are fused together by either a bridge of renal parenchyma or fibrous tissue; in the overwhelming majority, the lower poles are fused. In crossed renal ectopia, the kidney mass is located on the side opposite to its insertion in the bladder. Multiple configurations of crossed ectopia with and without fusion have been described.

The preoperative objective for the various renal anomalies is to image the renal mass adequately, delineate the course of the ureter, and establish the arterial and venous supply. The approach is simplified by the fact that most patients undergo abdominal/pelvic CT as part of the preoperative evaluation. The location and position of both the kidneys and ureters, like the position of the left renal vein, should be established as part of the review of every CT scan for patients with aneurysms. Formerly, it was recommended that patients with renal anomalies undergo preoperative arteriography to confirm the location and number of renal arteries. However, this information can now be obtained from the CT arteriogram, which is now part of the routine preoperative evaluation.

Patients with renal anomalies can safely undergo repair of an abdominal aortic aneurysm using either an open or endovascular approach.^{271–273} However, the anomalies must be factored into the operative plan. The specific operative approach depends on the location of the renal mass, blood supply, course of the ureters, and presence of fusion. A left-sided retroperitoneal or transperitoneal approach with medial

visceral rotation is the most helpful for open repair, particularly in patients with a horseshoe kidney. A standard transperitoneal approach with transection of the fused parenchyma can be used in patients with a horseshoe kidney, although this may be associated with both significant bleeding and a urine leak and, therefore, is discouraged. The frequently encountered multiple renal arteries can be handled most expeditiously by using a Carrel patch technique, in which a cuff of aorta including the renal artery orifices is reimplanted into the aortic graft after completion of the proximal anastomosis. Endovascular repair is possible in many cases, with the feasibility dictated by the location of the renal arteries in addition to the other standard anatomic considerations. Use of the endovascular approach may require covering at least one of the renal vessels and has been associated with loss of some renal parenchyma.²⁷¹

Coexistent Renal or Visceral Artery Occlusive Disease

Coexistent renal or visceral artery occlusive disease is frequently found in patients undergoing abdominal aortic aneurysm repair. The optimal management of patients with coexistent lesions remains unresolved. The options include repair of the aneurysm alone, simultaneous repair of the aneurysm and revascularization of the renal or visceral vessels, and staged repair, with either aneurysm repair or revascularization performed first. Furthermore, the specific treatment options include both open and endovascular alternatives for the aneurysm repair and visceral/renal revascularization (i.e., angioplasty/stent). The rapid expansion of the endovascular technologies has afforded effective, safe approaches that have widely replaced open surgical revascularization for both renal and visceral artery lesions. Regardless, the optimal approach represents a balance between the indications for the procedure and the associated added risk.

Renal/visceral revascularization is mandatory at the time of open aneurysm repair if the affected vessels are involved in the aneurysm, as in a suprarenal aneurysm or a horseshoe kidney. More commonly, a lower pole or accessory renal artery may come off the aneurysm. The decision to perform a concomitant revascularization with either reimplantation or a bypass graft in this setting depends on the size of the vessel and the quantity of kidney parenchyma perfused. Revascularization is recommended for larger vessels (>2 mm) that supply a significant portion of the renal mass. The presence of any accessory renal arteries should factor into the operative plan and the general feasibility for endovascular repair. Covering small, accessory renal arteries has been reported to be safe, although it must be appreciated that this approach sacrifices some renal parenchyma.²⁷⁴

Combined aneurysm repair with renal or visceral artery revascularization may be justified if the indications for renal or visceral artery revascularization are satisfied. The traditional indications for renal revascularization included poorly controlled hypertension in a patient with a significant renal artery stenosis and rapidly progressive renal insufficiency in a patient with adequate renal mass and bilateral renal artery stenoses. However, the antihypertensive agents have improved so much that renal revascularization is currently reserved for patients with poor blood pressure control despite optimal medical therapy encompassing three or more, separate medications.²⁷⁵ The indication for renal revascularization in patients with atherosclerotic renal artery disease and progressive renal insufficiency is even less compelling although the focus of several ongoing randomized trials. Endovascular treatment of the renal artery stenoses (when indicated) can be performed prior to open aneurysm repair or simultaneous with the endovascular approach. Although feasible, simultaneous open aneurysm

repair and renal artery bypass is associated with a significant increase in the operative mortality rate relative to the aneurysm repair alone.^{276,277}

The traditional indications for mesenteric revascularization include symptoms of chronic mesenteric ischemia and critical stenosis of either the superior mesenteric artery alone or two of the three visceral vessels. Patients with chronic mesenteric ischemia and abdominal aortic aneurysms should have their visceral occlusive disease corrected prior to aneurysm repair. Repairing the aneurysm first potentially increases the risk of developing acute mesenteric ischemia, while the simultaneous open approach is likely prohibitive given the significant morbidity/mortality associated with open mesenteric revascularization alone.^{278–280} Endovascular treatment with balloon angioplasty and stenting is probably the optimal treatment for the visceral lesions in this setting because of its simplicity despite the concerns about its longer-term durability.^{281,282}

The optimal treatment for patients with aneurysms and *asymptomatic* renal or visceral artery lesions remains even less clear. Natural history studies with the use of both arteriography²⁸³ and duplex scanning²⁸⁴ have suggested that significant renal artery stenoses are preocclusive lesions that may merit intervention. However, analysis of patients with asymptomatic renal artery stenosis who underwent aortic reconstruction found that the natural history of the renal artery lesions is fairly benign when untreated and is associated only with an increase in the antihypertensive requirements.²⁸⁵ Little is known about the natural history of asymptomatic mesenteric occlusive lesions. However, a recent small report suggested that patients with asymptomatic severe mesenteric occlusive disease involving all three visceral vessels have a high incidence of bowel infarction.²⁸⁶ Consideration should be given for mesenteric revascularization prior to aneurysm repair in patients with severe visceral artery occlusive disease due to the potential risk of mesenteric infarction at the time of aneurysm repair as noted earlier.

Additional Concurrent Intra-abdominal Disease

The finding of an abdominal aortic aneurysm and an additional intra-abdominal process that may require operative repair is a frequent event. A second surgical problem may be identified as part of the preoperative evaluation or discovered at the time of the exploratory laparotomy during open aneurysm repair. Alternatively, an abdominal aortic aneurysm may be identified during the surgical treatment of another problem. No algorithms have been defined for the management of such concurrent problems, and the overall approach requires a modicum of clinical judgment. Options include simultaneous repair or staged repair with repair of the abdominal aortic aneurysm as either the first or second procedure. The approach depends on the risk for aneurysm rupture, natural history of the second surgical problem, and potential for infection of the prosthetic graft during simultaneous repair. Notably, both the laparoscopic and endovascular approaches have impacted the approach to patients with combined problems due to their reduced morbidity and mortality that facilitates a more rapid, definitive treatment.

The generic recommendation for patients with an abdominal aortic aneurysm and an additional intra-abdominal surgical problem is that the most life-threatening or imminent problem be addressed first. The natural history of untreated abdominal aortic aneurysm has been defined reasonably well and has been outlined extensively earlier in this chapter. It has been suggested that the risk for aneurysm rupture is increased after major intra-abdominal surgery and that it is potentially related to an increase in collagenase activity.²⁸⁷ However, this reported increased rupture risk is speculative and should not

necessarily be factored into the decision algorithm. The management of concurrent colon cancer and abdominal aortic aneurysm is a frequent treatment dilemma that provides an excellent illustration of the approach to these problems. Indeed, the reported incidence of colon cancer and an abdominal aortic aneurysm occurring simultaneously ranges from 0.5% to 2.1%.¹⁸¹ The treatment principles promulgated by Szilagyi et al.²⁸⁸ include the following: (a) aneurysm repair first in the presence of rupture; (b) colon resection first in the presence of hemorrhage, perforation, or obstruction; (c) aneurysm repair first in the presence of a large aneurysm and a small colon cancer; (d) colon resection first in the presence of a large colon cancer and a small aneurysm.

Simultaneous abdominal aortic aneurysm repair and cholecystectomy is probably safe for patients with cholelithiasis or evidence of chronic cholecystitis. The safety of these simultaneous procedures has been documented in several series, and the concerns about an increased incidence of aortic graft infection have not been substantiated.²⁸⁹ Advocates of the simultaneous approach justify the cholecystectomy by the potential requirement for a cholecystectomy in the future and the morbidity and mortality associated with cholecystitis after aneurysm repair.²⁸⁹ Although a consensus is not found in the literature, simultaneous abdominal aortic aneurysm repair and cholecystectomy are recommended only if evidence of chronic cholecystitis or multiple small stones is present. Regardless, the cholecystectomy and other simultaneous procedures should not be performed until after the aneurysm repair is completed and the retroperitoneum closed in an attempt to reduce the hypothetical risk for graft infection.

The safety and utility of other simultaneous procedures remain poorly defined, although a wide range of procedures have been combined with open aneurysm repair.^{178–181} The repair of ventral hernias is often mandatory to achieve a tension-free abdominal closure and should be viewed more as an extension of the aneurysm repair than as a simultaneous procedure. Inguinal hernias may be repaired at the time of aneurysm repair, but it is uncertain whether the small risk associated with a subsequent procedure at a later date offsets the obligatory additional time for the simultaneous repair. Appendectomy²⁹⁰ and small-bowel excision for Meckel diverticulum²⁸⁹ have been reported to be safe when performed concomitantly with aneurysmectomy, although the natural history of the associated underlying problems in the usual age group of patients undergoing abdominal aortic aneurysm repair is relatively benign.

CHAPTER 101 ■ LOWER EXTREMITY ANEURYSMS

AMY B. REED

KEY POINTS

- 1 Femoral and popliteal aneurysms may be asymptomatic, being an incidental finding on routine physical examination, but they are potentially limb threatening and are frequently associated with life-threatening abdominal aortic aneurysms.
- 2 Femoral artery aneurysms are the most common peripheral aneurysm if both true and false aneurysms are considered together.
- 3 Anastomotic aneurysms result from a disrupted suture line between a graft and the host artery.
- 4 Catheter-induced pseudoaneurysms result from failed hemostasis.
- 5 Popliteal artery aneurysms often develop limb-threatening complications if not treated, and results of surgical therapy are much better if treatment is undertaken prior to the development of complications.
- 6 Thrombolytic therapy is a useful adjuvant in patients presenting with acute limb ischemia secondary to occlusion of a popliteal artery aneurysm and the outflow arteries.

PERIPHERAL ANEURYSMS

- 1 Popliteal artery aneurysms are the most frequently encountered peripheral aneurysm. Their significance comes from their potential for limb-threatening complications, rather than rupture, and their association with life-threatening abdominal aortic aneurysms. True femoral artery aneurysms are rare, with iatrogenic and anastomotic pseudoaneurysms being more common.

Incidence

While the exact incidence of femoral and popliteal aneurysms is difficult to determine, the number being recognized is increasing. An aging population, increased arterial trauma, more common use of invasive therapies for vascular disease, and increased use of imaging modalities all contribute to the rise in number of peripheral aneurysms being diagnosed. In a screening study of men between the ages of 65 and 74 years, abdominal aortic aneurysms were identified in 4.9% of patients.¹ In patients with abdominal aortic aneurysms, 6.8% had femoral artery aneurysms and 9.6% had popliteal artery aneurysms.² Screening of men between the ages of 65 and 80 years identified popliteal artery aneurysms in 1%.³

An increasing number of false aneurysms—"pseudoaneurysms"—are occurring coincident with the increased use of catheter-based diagnostic and therapeutic interventions in addition to lower extremity bypass surgery. Pseudoaneurysms can be iatrogenic, infectious, or traumatic in nature and are identified by their lack of involvement of all three vessel wall layers, as is typically seen in true aneurysms. The incidence of pseudoaneurysm after diagnostic procedures is approximately 0.3% and slightly higher at 1.5% after therapeutic procedures, in general due to use of larger sheaths.⁴ False aneurysms can also arise from trauma during surgery, such as orthopedic procedures. Femoral pseudoaneurysms develop after 0.08% of total hip arthroplasties, and popliteal aneurysms arise following 0.17% of total knee arthroplasties.⁵

Degenerative (often called atherosclerotic) femoral and popliteal artery aneurysms are encountered far more frequently in men than women. The male-to-female ratio in patients with femoral and popliteal aneurysms is about

30:1.^{6,7} This predilection for men is markedly different from aortic aneurysms where the male-to-female patient ratio is approximately 4:1.²

Pathogenesis

The cause of femoral and popliteal artery aneurysms has changed significantly since they were first recognized centuries ago. Once primarily mycotic or syphilitic in origin, most true aneurysms in the 21st century have a degenerative cause commonly called *atherosclerotic aneurysms*, whereas false aneurysms usually follow surgery or trauma. True tibial artery aneurysms are rare.

The cause of degenerative aneurysms of the femoral and popliteal vessels is not clear. One factor believed to contribute to aneurysm formation is turbulent flow beyond a relative stenosis resulting in poststenotic dilatation beyond the inguinal ligament at the groin or beyond the tendinous hiatus of the adductor magnus or the arcuate popliteal ligament and the heads of the gastrocnemius muscle at the popliteal level. Arterial wall fatigue resulting from vibration and turbulence proximal to a major branching or caused by stress during hip and knee flexion may also contribute to aneurysm formation.

The frequent occurrence of multiple peripheral aneurysms in the same patient suggests a systemic abnormality in the arterial wall, which promotes aneurysmal degeneration at locations where hemodynamic or mechanical factors put unusual stress on the arterial wall. The multiple factors that contribute to aneurysmal degeneration are reviewed in Chapter 100 and are felt to contribute to degenerative femoral and popliteal aneurysms, as well as aortic aneurysms. The presence of an inflammatory infiltrate has been noted in the wall of femoral and popliteal aneurysms, similar to aortic aneurysms.⁸ The exact role of this inflammatory process, with potential release of reactive oxygen species and matrix metalloproteinases, is unknown. Apoptosis of smooth muscle cells may also play a role in the formation of aneurysms by limiting the ability of the arterial wall to respond to the degenerative process.⁹ These factors, however, do not explain the male predilection for femoral and popliteal aneurysm formation. X-linked genetic abnormalities for aneurysm formation have not been noted in humans.

Clinical Manifestations

Femoral and popliteal aneurysms are often asymptomatic, being detected on routine physical examination by a bounding, expansile pulse. Both femoral and popliteal artery aneurysms, however, may be accompanied by symptoms of local fullness, pain caused by pressure on the adjacent nerve, limb edema, and venous distention or thrombosis caused by compression of the adjacent vein. Patients may also present with lower extremity ischemia with intermittent claudication, rest pain, or gangrene secondary to complications of a femoral or popliteal aneurysm, including thrombosis or distal embolization. Because the natural history and complication rate in femoral and popliteal aneurysms differ, they are considered separately here.

FEMORAL ARTERY ANEURYSMS

- 2 Femoral artery aneurysms are the most common peripheral aneurysm if both true and false aneurysms are considered together, with the vast majority being false aneurysms. Their clinical importance rests in the fact that they are limb-threatening lesions and can jeopardize the viability of the leg if thrombosis, embolization, or rupture occurs. The vast majority of true aneurysms are degenerative lesions commonly called *atherosclerotic aneurysms*, whereas false aneurysms include anastomotic, traumatic, and mycotic lesions. Rarely, femoral aneurysms develop secondary to connective tissue disorders. The femoral region is the most common site for both anastomotic aneurysms and mycotic aneurysms associated with trauma; so the presentation and surgical repair of these lesions are discussed.

Degenerative (Atherosclerotic) Aneurysms

Incidence. The exact incidence of degenerative (atherosclerotic) common femoral artery aneurysms in the general population remains undefined. They are found in 6.8% of all patients with abdominal aortic aneurysms, and 85% of patients with femoral artery aneurysms have abdominal aortic aneurysms.^{2,6}

Pattern of Disease. Femoral aneurysms most frequently affect the common femoral artery. They may be classified as *type I*, those limited to the common femoral artery, or *type II*, those involving the orifice of the profunda femoris artery.¹⁰ Type I and type II aneurysms occur with nearly equal frequency. This classification becomes important in reference to vascular reconstructive procedures, with type II aneurysms requiring more complex reconstructions to ensure continued patency of both the superficial and profunda femoris arteries. Isolated lesions of the profunda femoris artery are rare (2% of femoral artery aneurysms) and are prone to rupture because they are difficult to diagnose at the asymptomatic stage. Isolated superficial femoral artery aneurysms are also uncommon, but one third of patients present with rupture and one quarter with thrombosis.¹¹

Femoral artery aneurysms can be limb-threatening lesions and are frequently associated with limb-threatening popliteal aneurysms and life-threatening abdominal aortic aneurysms. Multiple aneurysms are common in patients with femoral artery aneurysms. In a series of 100 patients with degenerative femoral artery aneurysms seen at a single institution, 72% of patients had bilateral femoral artery aneurysms.⁶ In addition, aortoiliac aneurysms were detected in 85% of patients, thoracic aortic aneurysms in 6%, and popliteal aneurysms in 44%, of which 55% were bilateral.

Clinical Manifestations. The typical patient with a degenerative femoral artery aneurysm is a male in his 60s or 70s with the usual risk factors for atherosclerosis. Of these patients, 86%

are cigarette smokers, 36% have hypertension, and 14% have diabetes mellitus.⁶ Associated cardiovascular disease is common, with clinical manifestations of coronary artery disease and cerebrovascular disease present in 34% and 7%, respectively.

The clinical manifestations of femoral artery aneurysms cover the spectrum from asymptomatic to severe ischemia of the lower extremity. Although 40% of patients are asymptomatic at the time of diagnosis, the majority present with local symptoms or complaints of lower extremity ischemia.⁶ Local pain or observation of a groin mass is the only complaint in 18% of patients. Lower extremity venous disease is present in 8%, being attributable to venous obstruction by the femoral artery aneurysm in 4%; but venous obstruction is rarely the sole sign of an aneurysm. Lower extremity ischemic symptoms of claudication, rest pain, or gangrene are present in 42% of patients and often lead to the diagnosis of the femoral artery aneurysm.

As with aneurysms in other locations, femoral artery aneurysms may be complicated by embolization, thrombosis, or, rarely, rupture. Peripheral embolization may be identified incidentally on angiography or produce signs as mild as spotty discoloration of the toes to as severe as peripheral gangrene. Although embolization is reported in about 10% of aneurysms, the femoral artery aneurysm is not necessarily the source of these emboli because many patients have a concomitant popliteal aneurysm.⁶ In larger clinical series, 1% to 16% of patients with degenerative femoral artery aneurysms present with an acute thrombosis, whereas 1% to 16% have a chronically thrombosed lesion.^{6,10} Rupture is reported in 1% to 14% of aneurysms.^{6,10}

Natural History. The natural history of degenerative femoral artery aneurysms is poorly defined. Most publications have reviewed aneurysms that were treated surgically. A small asymptomatic femoral artery aneurysm does not appear to pose the same threat to the limb as does a popliteal artery aneurysm. In a series of 100 patients with atherosclerotic femoral artery aneurysms, serious limb-threatening complications were documented in only 2.9% of the 105 aneurysms followed nonoperatively.⁶

Diagnosis. In most cases the diagnosis of femoral artery aneurysm is suspected by the finding of a pulsatile groin mass on routine physical examination or during evaluation for vascular disease. If the femoral artery aneurysm is small or thrombosed, detection on physical examination may be difficult. Although a radiograph of the region may occasionally demonstrate the calcified rim of the aneurysm, only ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) can reliably establish the diagnosis of the femoral aneurysm. In addition, these modalities are useful in accurately defining the size of the lesion and evaluating associated aneurysmal disease in the distal aorta and popliteal regions. These findings are particularly important because life-threatening abdominal aortic aneurysms are missed on physical examination in 50% of patients with multiple aneurysms.¹² The diagnostic accuracy of arteriography is limited because it demonstrates only the residual lumen and an aneurysm filled with smooth mural thrombus may be missed, but the definition of the vascular anatomy of the lower extremity provided by angiography is helpful in planning the appropriate operative procedure (Fig. 101.1).

Treatment. Management of femoral artery aneurysms can be found in Algorithm 101.1. Operative treatment is indicated for aneurysms causing local symptoms and presenting with limb-threatening complications. Asymptomatic aneurysms greater than 2.5 cm in diameter should also be repaired unless the patient is a prohibitive risk for operative intervention. In patients with small, asymptomatic aneurysms, observation may be appropriate, particularly in the patient with multiple medical problems who would be high risk for surgery. When nonoperative management is selected, the size of the aneurysm should be documented by ultrasonography. The patient should be followed at regular intervals with ultrasound scans and

FIGURE 101.1. Arteriogram demonstrating bilateral femoral artery aneurysms that extend into the superficial femoral arteries. Unlike many patients with femoral artery aneurysms, this patient did not have an associated aortic aneurysm or popliteal aneurysms.

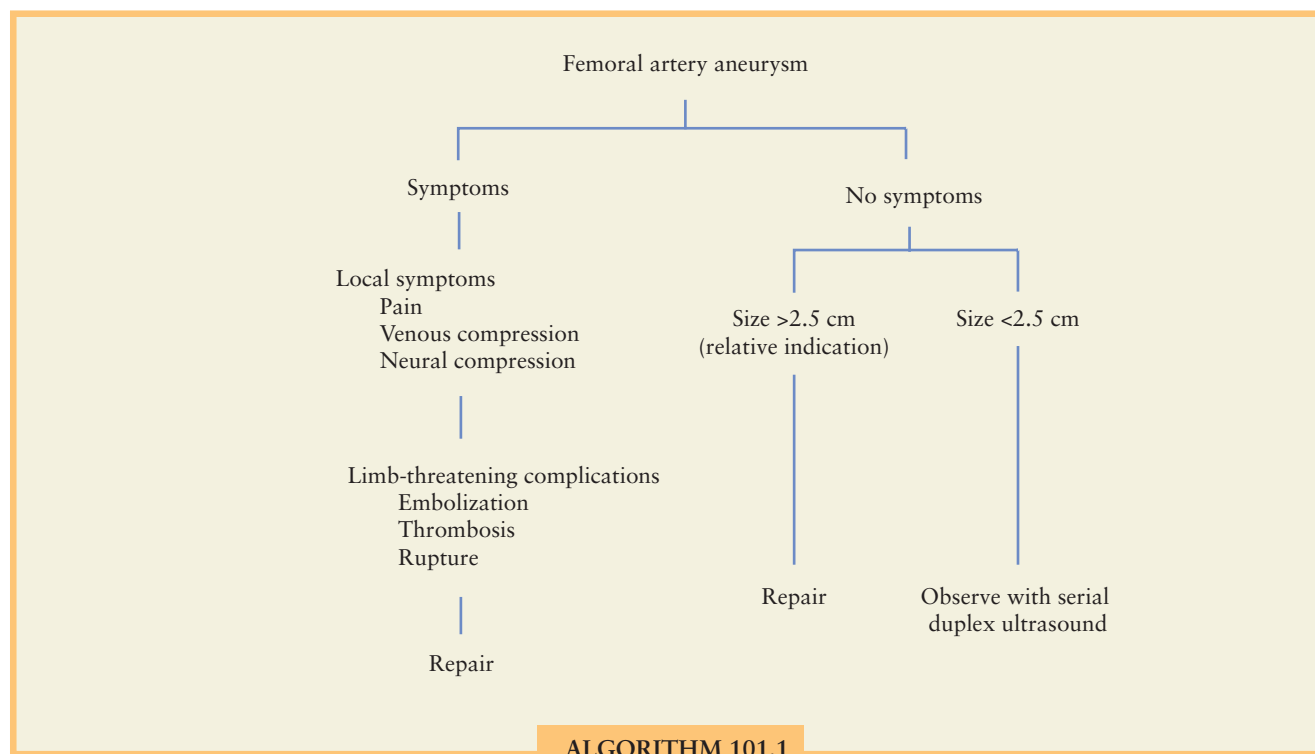

careful examination for occult complications. Operative treatment should be undertaken without undue delay if the femoral aneurysm enlarges, produces symptoms, or is complicated by embolization, thrombosis, or rupture.

Surgical Strategy. The operative approach is individualized based on associated aneurysmal disease. In patients with mul-

tle asymptomatic aneurysms, treatment is staged. The life-threatening aortic lesions are treated before limb-threatening femoropopliteal lesions. Femoral artery aneurysms are addressed after popliteal lesions unless the femoral aneurysm is repaired in combination with treatment of the aortic or popliteal aneurysm. If an aortofemoral bypass is necessary, the femoral aneurysm should be treated at the same time, to avoid later anastomotic aneurysm formation. The graft limb can be anastomosed into an interposition graft that has replaced the femoral aneurysm. Similarly, if a stent graft is placed for treatment of an abdominal aortic aneurysm in a patient with femoral artery aneurysms, the aneurysm should be repaired with an interposition graft. In patients with severe lower extremity ischemia, the femoral aneurysm is treated with an interposition graft, from which the proximal anastomosis of the required femoropopliteal or femorotibial bypass is based.

Technique. The operative procedure for treatment of an isolated femoral artery aneurysm is determined by aneurysmal involvement of the superficial and deep femoral arteries as well as by the existence of lower extremity occlusive disease. The femoral artery aneurysm is usually approached through a longitudinal groin incision. When addressing an unusually large aneurysm or a ruptured aneurysm, however, initial proximal control of the external iliac artery through a retroperitoneal approach is advisable. After proximal and distal arterial control is obtained, the aneurysm sac is opened and the atheromatous debris removed. Small aneurysms may be excised, but routine excision of large aneurysms is not recommended as these lesions can often be adherent to the adjacent vein and nerve. For type I aneurysms, the preferred treatment is reconstruction with an interposition graft of Dacron or expanded polytetrafluoroethylene with the proximal anastomosis at the distal external iliac artery or proximal common femoral artery and the distal anastomosis at the femoral bifurcation.

For type II aneurysms with patent superficial and profunda femoris arteries, an interposition graft to the profunda femoris artery with reimplantation of the superficial femoral artery is one

ALGORITHM 101.1

standard configuration. If the superficial femoral artery is chronically occluded and the patient has minimal symptoms, an interposition graft to the profunda femoris artery alone is sufficient. If the patient has severe lower extremity ischemia, this is typically followed by a standard distal reconstruction. If recent emboli or in situ thrombosis have occluded the outflow tract, percutaneous mechanical thromboembolectomy or catheter-directed thrombolytic therapy is useful before open arterial reconstruction is undertaken.

Results. Results of surgical therapy depend on the patency of the distal vasculature. More than 80% of asymptomatic patients have excellent long-term results, whereas 68% of those presenting with lower extremity ischemia achieve satisfactory long-term outcomes.⁶

Anastomotic Pseudoaneurysms

- 3 Incidence.** Anastomotic pseudoaneurysms result from a disrupted suture line between a graft and the host artery. The incidence varies with the location of the anastomosis and the type of graft that is used. Involvement of the femoral artery accounts for nearly 80% of these lesions, and 3% of all femoral anastomoses or 6% of femoral anastomoses after aortofemoral bypass develop this complication compared with 0.2% of aortic anastomoses.^{14,15} Patient factors that are associated with increased likelihood of developing a femoral anastomotic aneurysm after aortofemoral bypass include chronic obstructive pulmonary disease, current smoking, and postoperative groin wound infection.¹⁶ After infrainguinal bypass procedures, the incidence is higher with prosthetic grafts than with autogenous vein grafts, with 6% of femoral anastomoses developing aneurysms when Dacron is used compared with 0.9% when a vein graft is placed.¹⁴ Anastomotic pseudoaneurysms are a late complication of bypass procedures; the mean interval from primary procedure to recognition is more than 6 years.^{17,18}

Pathogenesis. Several factors contributing to anastomotic pseudoaneurysm formation have been identified, including weakness of the arterial wall, the type of graft material and suture utilized, the presence of infection, the method of construction of the anastomosis, and the stress on the suture line from hypertension, leg motion, or excess tension on the graft limb.^{14,17,18} Progressive degeneration of the recipient artery accounts for most anastomotic pseudoaneurysms, and an increased incidence has been noted following endarterectomy of the artery at the anastomosis. False aneurysms occur less frequently with saphenous vein grafts than synthetic vascular grafts, a reflection of more complete healing of autogenous tissue. With the use of monofilament synthetic suture, anastomotic pseudoaneurysms rarely result from a loss of suture integrity, although occasionally a broken suture is a factor in pseudoaneurysm formation. Although most anastomotic aneurysms are not accompanied by overt graft infection, occult infections with coagulase-negative *Staphylococcus* species may be an important factor in the development of anastomotic aneurysms.¹⁸ A higher incidence is noted in patients with wound healing complications, and the use of anticoagulants may increase such complications.

Clinical Manifestations. Femoral anastomotic pseudoaneurysms usually present as a pulsatile groin mass, which may or may not be accompanied by pain, redness, or symptoms of venous obstruction. Acute complications include hemorrhage, embolization, and occlusion. The latter may cause lower extremity ischemia with claudication, rest pain, or gangrene.

Diagnosis. The diagnosis of a false aneurysm is usually made on physical examination by the presence of a pulsatile groin

FIGURE 101.2. Arteriogram demonstrating bilateral femoral anastomotic aneurysms after an aortofemoral bypass and a left femoropopliteal bypass.

mass in a patient who has undergone a femoral arterial reconstructive procedure. The differential diagnosis includes nonpulsatile groin masses, such as hernia, lymphocele, or abscess, through which pulsation is transmitted from an underlying normal femoral artery. Diagnosis of an anastomotic disruption in one region should raise suspicion of other anastomotic pseudoaneurysms because multiple lesions are found in at least 30% of patients,¹⁷ and their presence suggests infection. Evaluation of an anastomotic aneurysm includes ultrasonography or CT of all anastomoses of the graft. Angiography done prior to repair of the anastomotic aneurysm is helpful in defining the proximal and distal arterial anatomy (Fig. 101.2).

Treatment. Because of the progressive nature of anastomotic pseudoaneurysms, surgical treatment is undertaken for all lesions except those which are small (<2 cm) in high-risk patients. Principles of surgical therapy are those of primary aneurysms: obtain proximal and distal control and replace the aneurysmal segment. Securing proximal control often requires dividing the inguinal ligament to isolate the graft limb. Distal control is most easily obtained using intraluminal balloon catheters. If intrinsic arterial disease requires extension of the graft distally on the profunda femoris or superficial femoral artery, these arteries can be identified by dissection through unscarred tissue distal to the previous exposure. After débridement of the degenerated artery, an interposition graft is placed between the prosthetic graft limb and the healthy native artery. Cultures of the graft and vessel wall are essential to exclude infection as an etiologic factor in the development of the anastomotic aneurysm. If infection is obvious at the time of surgery, the approach is the same as that of any infected graft with removal of infected prosthetic material and reestablishment of blood flow, if necessary, with a bypass through an uninfected tissue route, such as an obturator, lateral femoral, or axillofemoral bypass.

Results. Results of elective operations on uncomplicated anastomotic aneurysms are excellent with 2% operative mortality, 97.5% graft patency at 2 years, and 2% amputation within 2 years of surgery.¹⁷ Recurrence is reported in less than

16% of cases.^{14,15} Patients presenting with aneurysms complicated by hemorrhage, occlusion, or embolization have significantly increased operative morbidity and mortality.

Femoral Pseudoaneurysms

Incidence. The femoral artery is the preferred site for percutaneous access for both diagnostic and therapeutic angiography, including endovascular grafts. In recent years, diagnostic studies for coronary and peripheral artery occlusive disease have increased as have the subsequent endovascular interventions, which have resulted in an increased number of femoral pseudoaneurysms. Because interventional techniques often require prolonged arterial cannulation, large-bore sheaths, and anticoagulation, they are accompanied by a higher rate of arterial complications than are diagnostic studies. Review of recent experience shows that pseudoaneurysms form after about 0.3% of diagnostic catheterizations and about 1.5% of catheter-based therapeutic procedures.⁴ The use of percutaneous closure devices decreases the risk of developing a pseudoaneurysm at the arterial access site for an interventional procedure by a factor of 10 to an incidence of about 0.1%.^{19,20}

Pathogenesis. Pseudoaneurysms from iatrogenic catheter trauma are classically defined as collections of blood in continuity with the arterial system that is not enclosed by all three layers of the arterial wall. These lesions form because of failed hemostasis at the arterial wall defect created by sheath insertion. Normally, hemostasis, aided by direct focal application of pressure or hemostatic devices, seals the defect promptly, and the arterial wall repairs itself. When hemostasis is not successfully obtained, blood under arterial pressure leaks from the artery, dissects surrounding tissue planes, and forms what is perceived on physical examination to be a pulsatile mass. The gross findings at surgery are a blood-filled cavity surrounded by a capsule. Like all pseudoaneurysms, these lesions can cause symptoms by rupture or compression of surrounding structures.

Diagnosis. The diagnosis of femoral pseudoaneurysm is suspected when a pulsatile groin mass is noted after arterial catheterization. The differential diagnosis includes hematoma, lymphadenopathy, and abscess. Arterial duplex scanning or CT

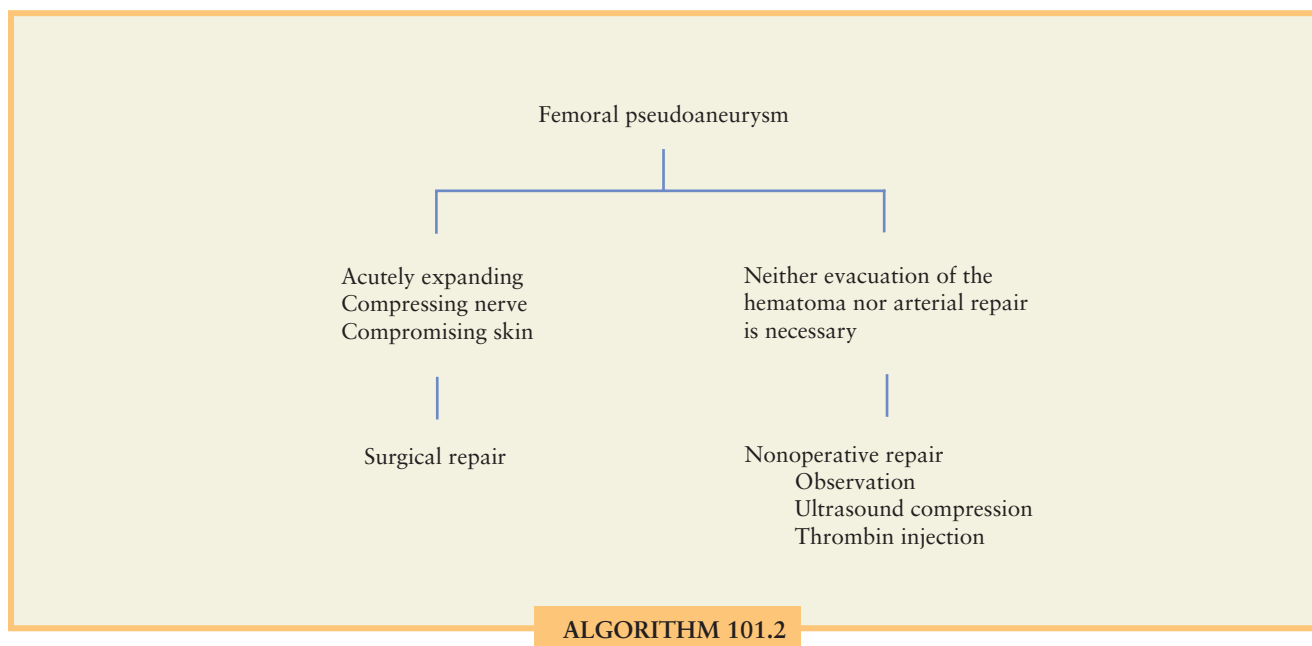

is typically used to establish the diagnosis, differentiate pseudoaneurysm from hematoma, and aid in defining the communication between the mass and the arterial lumen. Color-flow duplex scanning is the diagnostic test of choice, providing accurate diagnosis, localization, and sizing of the false aneurysms.

Natural History. Color-flow duplex scanning has been used to define the incidence and natural history of pseudoaneurysms after percutaneous transluminal coronary angioplasty.²¹ Many pseudoaneurysms will thrombose spontaneously within 4 weeks; however, this is less likely to occur in anticoagulated patients and those with pseudoaneurysms more than 2.0 cm in diameter. About 30% of patients with pseudoaneurysms will require intervention.²²

Treatment. Therapy of femoral pseudoaneurysms is influenced by aneurysm size and symptoms, and whether the patient requires continuous anticoagulation (Algorithm 101.2). Surgical therapy is mandatory for all pseudoaneurysms that are acutely expanding, compressing adjacent nerves, or compromising the overlying skin. Proximal and distal arterial control is obtained, and the arterial defect is repaired directly, rarely requiring placement of more than one to two sutures.

An excellent alternative to a surgical approach, when urgent evacuation of the hematoma and arterial repair are not required, is the use of ultrasound-directed compression therapy or thrombin injection into the false aneurysm. The pseudoaneurysm is identified with a color-flow ultrasound probe and then compressed with the scan head. Real-time observation of flow in the underlying artery allows compression of the pseudoaneurysm while maintaining flow in the native vessel to prevent arterial occlusion.²³ Pseudoaneurysm thrombosis is documented by absence of flow signals on release of scan-head pressure in the case of compression therapy. While effective, this can often be quite uncomfortable for the patient and take upwards of 30 minutes of compression by the vascular technologist.

Another nonoperative treatment option of femoral pseudoaneurysms is percutaneous ultrasound-guided injection of 0.5 to 1.0 mL thrombin (1,000 U/mL) into the pseudoaneurysm away from the neck of the aneurysm.^{23–25} Thrombin injection avoids the discomfort of prolonged compression and is effective in anticoagulated patients. Continuous ultrasonographic imaging is used to monitor thrombosis of the pseudoaneurysm.

ALGORITHM 101.2. Management of femoral pseudoaneurysm.

Results. Ultrasound-guided compression therapy for femoral pseudoaneurysms results in thrombosis in 80% to 90% of cases. The initial success rate is similar in patients who are anticoagulated and in those who are not, although long-term success appears to be better in patients not receiving anticoagulant therapy. In one of the largest series of pseudoaneurysms treated with ultrasound-guided compression, thrombosis was achieved in 86% of anticoagulated patients and in 98% of those not anticoagulated, with a 20% recurrence rate in less than 24 hours in anticoagulated patients.²⁶ Success using this therapeutic modality requires a knowledgeable ultrasonographer and meticulous postcompression follow-up.

Thrombin injection to induce thrombosis of pseudoaneurysms is successful in 94% to 98% of patients, with thrombosis occurring in less than 1 minute.^{23–25} This technique can be complicated by arterial thrombosis if an excessive volume of thrombin is used and may not be appropriate for pseudoaneurysms with large necks. Remote thromboembolic events are rare and probably are not a result of a systemic effect of the thrombin. Allergic reactions to bovine thrombin occasionally occur. Large pseudoaneurysms, greater than 8 cm in diameter, and an associated arteriovenous fistula (AVF) are predictors of failure with thrombin injection.²⁷

Mycotic Aneurysms

The term *mycotic aneurysm* is currently used to refer to any infected aneurysm. Mycotic aneurysms today are often a complication of parental drug abuse, but can follow arterial trauma of any form, including invasive diagnostic and therapeutic procedures. In the past, septic emboli from bacterial endocarditis were a major cause of mycotic aneurysmal degeneration, but this is less common today. With the advent of antibiotics, aneurysms secondary to syphilis or tuberculosis are rare. With the change in cause, the location of mycotic aneurysms has shifted from central to peripheral arteries, with the femoral artery being the most common site.^{29,30} The importance of mycotic aneurysms comes from their propensity to rupture.

Pathogenesis. The pathogenesis of mycotic aneurysms can be divided into four major categories, although other less common causes also exist.²⁹ First, septic emboli from bacterial endocarditis may lodge in normal arteries, causing infection that weakens the arterial wall, resulting in aneurysm formation. These lesions are often multiple. Second, during an episode of bacteremia, microorganisms may lodge in a preexisting atherosclerotic plaque or aneurysm and begin to multiply with the same result. A third cause of mycotic aneurysms is the contiguous spread of bacteria from a local abscess. The inflammatory process destroys the arterial wall, causing pseudoaneurysm formation. Finally, trauma to the artery with concomitant contamination may result in formation of an infected pseudoaneurysm. This mechanism of mycotic aneurysm formation is being seen more frequently, coincident with the increased use of catheter-based procedures. Bacteria may be introduced concomitantly with needle puncture or by migration during prolonged arterial catheterization. Mycotic aneurysms accompanying drug abuse may be secondary to direct contamination of the arterial wall, or they may result from destruction of the vessel wall by a local abscess.

The bacteriology of arterial infections depends on the cause of the lesion. Aneurysms secondary to bacterial endocarditis grew *Pneumococcus*, *Streptococcus*, and *Enterococcus* species most frequently in the past, but recently *Staphylococcus*, *Salmonella*, *Escherichia coli*, and *Proteus* organisms also have been cultured.³⁰ *Staphylococcus aureus* is the most common pathogen in mycotic femoral artery aneurysms secondary to trauma and drug abuse, occurring in more than 65% of cases.³¹ In this population, at least 50% of the *S. aureus* organisms are resistant to methicillin.

Clinical Manifestations. The typical patient with a mycotic femoral aneurysm presents with a history of chills and fever and a tender, enlarging, pulsatile groin mass. The patient may have a history of intravenous drug use, recent arterial catheterization, penetrating trauma, or bacterial endocarditis. Local signs of infection, including tenderness, erythema, and warmth, are noted on physical examination. Lower extremity edema may occur secondary to venous or lymphatic obstruction. Petechial skin lesions, splinter hemorrhages, cutaneous abscesses, and septic arthritis may occur as a result of emboli originating from a mycotic aneurysm. A “sentinel bleed” may occur and signals impending rupture and life-threatening hemorrhage. Emergency surgery is indicated.

Diagnosis. The diagnosis of a mycotic aneurysm is usually straightforward, but distinguishing an abscess adjacent to the femoral artery from a femoral mycotic aneurysm may be difficult. In the patient with a pulsatile groin mass, laboratory findings including a leukocytosis, elevated erythrocyte sedimentation rate, and positive blood cultures are suggestive, but not specific, for a mycotic aneurysm. Multiple blood cultures or downstream arterial blood cultures may be necessary to yield positive results. Ultrasonography and CT angiography are helpful in establishing the diagnosis of an aneurysm (Fig. 101.3), but lack precision in distinguishing infected from bland aneurysms. The diagnosis of a mycotic aneurysm is confirmed at operation by demonstration of organisms on Gram stain or by positive cultures of the aneurysm wall.

Treatment. Mycotic aneurysms represent a serious life- and limb-threatening disease because their natural history is one of expansion and rupture. Therefore, mycotic aneurysms should be addressed surgically. The goal of treatment is eradication of the infection by excision of the aneurysm and débridement of adjacent infected tissue as well as by long-term antibiotic therapy. Secondly, adequate distal circulation must be restored. Before operative intervention is performed, the patient is started on antibiotics that are modified based on sensitivity testing of intraoperative cultures. Stent grafts have been used in selected cases of mycotic aneurysms when other approaches were not feasible; however, concern about latent infection of the stent graft oftentimes renders this more of a bridging technique than a long-term solution.

FIGURE 101.3. Computed tomography scan of an infected femoral anastomotic aneurysm that was diagnosed 5 years after aortofemoral graft placement.

The complexity of the operative procedure varies with the location and extent of the mycotic aneurysm. Although a direct approach to the femoral artery may be taken, a retroperitoneal exposure of the distal external iliac artery for proximal control is sometimes preferred for large or proximal femoral lesions to avoid excessive hemorrhage. When an infected femoral artery aneurysm is confined to only one arterial segment (common, superficial, or deep femoral artery), the aneurysm is excised and the proximal and distal arteries are ligated in emergent situations. In these cases in which an isolated arterial segment is ligated, severe ischemia resulting in amputation is unusual. In more than 50% of cases, however, the mycotic aneurysm involves the femoral artery bifurcation, and treatment requires resection of the femoral bifurcation and débridement to healthy arterial wall. The distal external iliac or proximal common femoral artery as well as the superficial and deep femoral arteries are oversewn with nonabsorbable monofilament suture. This results in significant ischemia in most patients, but with the patient heparinized, symptoms gradually improve as collateral circulation increases. The majority of patients will not need revascularization for limb salvage,³² but up to one third of patients will have limb-threatening ischemia.³¹ In patients in whom sepsis can be adequately controlled at the initial procedure, aggressive débridement may be followed by immediate revascularization using autogenous saphenous vein graft as the conduit and covering the graft with a sartorius muscle flap.³¹ Another option is to observe patients for 24 hours after arterial ligation and selectively revascularize only those patients in whom limb-threatening ischemia persists. Use of prosthetic material is avoided because of the high incidence of early and late septic complications, although it can occasionally be necessary through uninfected tissue planes such as the obturator or lateral femoral route. Antibiotics are begun preoperatively and continued for at least 6 weeks postoperatively.

POPLITEAL ARTERY ANEURYSMS

- 5** Popliteal aneurysms are limb-threatening lesions, the vast majority of which are degenerative in etiology. Occasionally, anastomotic or traumatic popliteal aneurysms, and rarely mycotic aneurysms, are encountered in contemporary clinical practice. The remainder of this section addresses only popliteal aneurysms that are degenerative in etiology.

Incidence

Popliteal artery aneurysms are the most common degenerative true peripheral aneurysm. They occur slightly more frequently than femoral artery lesions; however, popliteal aneurysms are relatively unusual compared to abdominal aortic aneurysms. Aortic aneurysms are diagnosed with about 10 times the frequency of popliteal aneurysms.^{33,34}

Pattern of Disease

Like patients with femoral artery aneurysms, multiple aneurysms occur frequently in patients with popliteal aneurysms. About 60% to 70% of patients have bilateral popliteal aneurysms, and 55% have extrapopliteal aneurysms.^{35,36} Abdominal aortic aneurysms are encountered in 40% to 50%, and are particularly common in patients with bilateral popliteal aneurysms, of whom about 70% have aortic aneurysms.³⁵⁻³⁷ Femoral artery aneurysms occur in nearly 40% of patients.^{36,37} The importance of this multiplicity of aneurysms is that they may be missed on physical examination. Therefore, their presence must be determined by other studies, such as ultrasonography or CT, so that potentially life-threatening abdominal aortic aneurysms and other limb-threatening lesions are identified and managed appropriately. Even when popliteal aneurysms are initially asymptomatic, patients will develop symptoms at a mean rate of 14% per year, and one third will develop

complications requiring emergent intervention within 5 years, resulting in poorer outcomes for both life and limb.^{38,39}

Clinical Manifestations

The typical patient with a popliteal aneurysm is a male in his 60s or 70s with the usual risk factors for atherosclerosis. Of patients with popliteal aneurysms, 50% to 75% are smokers, 40% to 60% have hypertension, and about 15% have diabetes mellitus.^{35-37,40} Other manifestations of cardiovascular disease are also common, with 10% of patients having manifestations of cerebrovascular disease and more than 40% having evidence of significant cardiac disease.³⁷

The clinical manifestations of popliteal artery aneurysms range from an asymptomatic pulsatile mass to severe lower extremity ischemia. About 40% of patients are asymptomatic at diagnosis.⁷ More than 50% of patients present with symptoms of limb ischemia, usually claudication, but the ischemia may be more advanced and manifested as rest pain or gangrene. Local symptoms, including sensation of a mass, local pain, and leg swelling or phlebitis secondary to compression of the adjacent vein, account for the remainder of symptoms. A popliteal artery aneurysm may be complicated by thrombosis, embolization, or, rarely, rupture. Thrombosis is reported in approximately 40% of patients,³⁶ and embolization occurs in about 25% of cases.³⁶ Some patients present with classic “blue toe syndrome,” but more commonly, repeated episodes of embolization occlude the outflow vessels and result in thrombosis of the aneurysm. Rupture occurs in fewer than 5% of popliteal aneurysms^{35,36}; in these cases, the hemorrhage is usually confined to the popliteal space, thus permitting surgical intervention and arterial reconstruction in a timely fashion.

Natural History

The natural history of popliteal aneurysms is not well defined because most series are composed primarily of aneurysms that have been treated surgically. In a review of 29 reports in the English literature published between 1980 and 1994, subgroups of patients were identified whose aneurysms had been observed.⁷ A mean of 35% of patients with conservative follow-up developed ischemic complications, and 25% of these required amputation even with modern therapy. Thus, a significant percentage of popliteal aneurysms will develop a complication if left untreated, and although this is not synonymous with limb loss, the amputation rate is high.

Diagnosis

The diagnosis of popliteal aneurysm is usually first suspected on physical examination. Palpation of the popliteal space with the knee flexed reveals a pulsatile mass in approximately two thirds of patients. Small aneurysms may not be palpable on physical examination, and if thrombosis has occurred the mass may be nonpulsatile. Radiographs of the knee demonstrating a calcified arterial wall occasionally suggest the diagnosis of a popliteal artery aneurysm, but it must be confirmed by duplex ultrasonography, CT (Fig. 101.4), or MRI. These diagnostic modalities can establish diagnosis of popliteal artery aneurysms and exclude other entities that could be responsible for a nonpulsatile popliteal fossa mass (tumor or Baker cyst). Ultrasonography, CT, or MRI is also useful in the detection of associated aneurysms, particularly abdominal aortic and femoral artery aneurysms. Angiography can be misleading in the diagnosis of aneurysms because intraluminal thrombus may obscure the true size of the vessel (Fig. 101.5); however, it is essential for visualization of the inflow and outflow vessels necessary for revascularization. CT angiography can be a non-invasive way to provide this information (Fig. 101.6).

FIGURE 101.4. Computed tomography of large right popliteal aneurysm with significant laminar thrombus present.

Treatment

Indications. Surgical treatment is indicated for all symptomatic and many asymptomatic aneurysms. Controversy exists regarding the optimal management of small asymptomatic popliteal aneurysms because the natural history is not well defined. The incidence of complications with popliteal artery aneurysms is high, and the occurrence of complications does not correlate with the size of the aneurysm because the most common complications are embolization and thrombosis, which are not size related. In fact, in some reports the average diameter of symptomatic aneurysms is smaller than asymptomatic lesions.^{41,42} These considerations, and the significantly higher limb loss rate after complications develop even when intervention is undertaken, have resulted in the recommendation for operative treatment when a popliteal aneurysm is diagnosed.

FIGURE 101.5. Arteriogram demonstrating a popliteal aneurysm associated with occlusion of the outflow tract presumably from repeated episodes of embolization. A bypass to the distal posterior tibial artery was successful.

FIGURE 101.6. Computed tomography arteriogram demonstrating right popliteal artery aneurysm and associated inflow and outflow.

The goals of surgical treatment are to eliminate the potential for complications and to preserve or restore adequate blood flow to the limb. In patients with multiple aneurysms, the operative approach must be individualized. Generally, the life-threatening aortic aneurysm is treated first, followed by repair of the popliteal aneurysm. On the other hand, if a limb-threatening complication has occurred, treatment of the popliteal aneurysm usually takes precedence, followed by expeditious aortic aneurysm repair.

Surgical Technique. Most popliteal aneurysms are easily approached through standard medial thigh and calf incisions for exposure of the distal superficial femoral artery and the distal popliteal artery, respectively. The proximal anastomosis will need to originate from the common femoral artery if the entire superficial femoral artery is aneurysmal. Occasionally, the posterior approach is preferred for lesions confined to the popliteal fossa, especially when accompanied by symptoms due to compression of adjacent structures. Most aneurysms are left in situ, bypassed using a segment of saphenous vein, and ligated proximally and distally. The conduit of choice for bypass is autologous saphenous vein, which is harvested from the thigh, reversed, and tunneled along the course of the popliteal artery. The proximal and distal anastomosis may be either end to end or end to side in configuration, with the aneurysm excluded from the circulation by proximal and distal ligatures. Ligation should be adjacent to the aneurysm to minimize the number of patent collaterals that are in continuity with the aneurysm.^{41,43} Late expansion and rupture of a bypassed and ligated popliteal aneurysm can occur when patent geniculate arteries continue to perfuse and pressurize the aneurysm. When the distal popliteal and proximal tibial vessels are occluded with recent emboli, they can sometimes be cleared using a balloon catheter or intraoperative thrombolytic therapy. Frequently, bypass grafts must be carried to the distal tibial arteries. Extensive femoral and popliteal aneurysms may require a femoral-popliteal or femoral-tibial bypass using in situ saphenous vein that originates from a prosthetic graft replacing a common femoral artery aneurysm.

Popliteal aneurysms have been treated by an endovascular approach. Small series show a primary patency rate of about 50% at 14 to 18 months^{13,44} and a cumulative patency of 74%,⁴⁵ suggesting that this approach should be reserved for the more high-risk patient who requires intervention.

The patient who presents with an acutely ischemic extremity secondary to popliteal aneurysm thrombosis is a management challenge. Popliteal aneurysms often thrombose because of repeated episodes of emboli to the outflow vessels, which results in their occlusion. An expeditious arteriogram may identify a suitable outflow vessel for the bypass graft. If no target vessel is identified, intra-arterial thrombolytic therapy should be initiated with the goal of lysing thrombus in the tibial arteries to identify a suitable outflow vessel for vascular reconstruction. Although the embolic process may be chronic, results with thrombolytic therapy followed by bypass of the aneurysm have been much better than surgical therapy alone for the patient with an acutely occluded aneurysm and severe leg ischemia.

Results. Excellent results are obtained in asymptomatic aneurysms with intact distal vasculature. Patients with thrombosed aneurysms or those in whom multiple episodes of embolization have occluded the tibial arteries have less optimal results. Operative mortality is in the 0% to 2% range, with asymptomatic patients faring better than those presenting with acutely symptomatic lesions.^{46,47} In patients undergoing revascularization before ischemic complications occur, 5- and 10-year graft patency rates are greater than 80% and limb salvage is 93% to 98%.^{35,48} Graft patency rates in patients undergoing surgery after developing complications of their aneurysms are 60% and 48% at 5 and 10 years, respectively, and limb salvage rates are 60% to 80%.^{35,48,49} Thrombolytic therapy, when successful, improves primary graft patency in patients presenting with acute limb ischemia.⁵⁰

CHAPTER 102 ■ VENOUS DISEASE

THOMAS W. WAKEFIELD AND MICHAEL C. DALSING

KEY POINTS

- 1 The diagnosis and treatment of acute and chronic venous disease has made significant advances in the last few years.
- 2 New drug therapies exist or are on the verge of impacting the treatment of acute DVT.
- 3 Chronic venous disease has experienced a resurgence of interest in the United States with new endoluminal and surgical interventions being investigated and used clinically.
- 4 Characterization of the disease is being scrutinized to allow for a better understanding of how treatment impacts patient outcomes.
- 5 The care of patients with venous disease is an active and maturing discipline within the realm of the surgical disciplines.

ACUTE VENOUS THROMBOEMBOLIC DISEASE**Incidence, Risk Factors, and Categories**

Venous thromboembolism (VTE), including deep venous thrombosis (DVT) and pulmonary embolism (PE), is a national healthcare concern. DVT affects more than 250,000 patients annually, whereas PE affects more than 200,000 patients per year. The incidence has remained constant since 1980 and increases with age.¹ The cost of treatment for both DVT and PE (termed VTE) is in the billions of dollars per year. Although the Virchow triad of stasis, vessel wall injury, and hypercoagulability has defined the events that predispose to DVT formation for the past 150 years, today the understanding of events that occur at the level of the vein wall, including the influence of the inflammatory response, on thrombogenesis is increasingly becoming recognized.

Acquired risk factors for VTE include increasing age, malignancy, immobilization, surgery and trauma, oral contraceptive use, hormone replacement therapy, pregnancy and the puerperium, neurologic disease, cardiac disease, obesity, and antiphospholipid antibodies.² Genetic risk factors include deficiencies of antithrombin, protein C and protein S, factor V Leiden, prothrombin 20210 A, blood group non-O, dysfibrinogenemia, dysplasminogenemia, hyperhomocystinemia, reduced heparin cofactor II activity, elevated levels of clotting factors (e.g., factors XI, IX, VII, VIII, X, and II), and elevations in plasminogen activator inhibitor-1 (PAI-1).³ When a patient presents with an idiopathic VTE, there is family history of VTE, there is recurrent thrombosis, or there is thrombosis in unusual locations, workup for a hypercoagulable state may be indicated (Table 102.1).^{2,3} Hematologic diseases associated with VTE include heparin-induced thrombocytopenia and thrombosis syndrome (HITS), disseminated intravascular coagulation (DIC), antiphospholipid antibody syndrome, thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and myeloproliferative disorders.

Most DVT affect the iliac, femoral, or popliteal lower limb veins. Presenting symptoms include unilateral leg pain and swelling, but some DVTs are silent, with the first manifestation a PE. A recent study of 5,451 patients with ultrasound-confirmed DVT revealed the most common comorbidities to be hypertension, surgery within 3 months, immobility within 30 days, cancer, and obesity.⁴

Venous Thromboembolism Diagnosis

- 1 **Deep Venous Thrombosis.** The diagnosis of DVT must be made with confirmatory laboratory testing, as patients will be asymptomatic at presentation in up to half the time. Patients complain of a dull ache or pain in the calf or leg. The most common physical finding is edema, although Wells et al.⁵ have classified patients into a scoring system that emphasizes physical presentation. Characteristics that score points include the presence of active cancer, paralysis or paresis, recent plaster immobilization of the lower extremity, being recently bedridden for 3 days or more, localized tenderness along the distribution of the deep venous system, the entire leg being swollen, calf swelling that is at least 3 cm larger on the involved side as compared to the noninvolved side, pitting edema in the symptomatic leg, and a history of previous DVT. With extensive proximal iliofemoral DVT there may be significant swelling, cyanosis, and dilated superficial collateral veins.

Massive iliofemoral DVT may result in the development of phlegmasia alba dolens (white swollen leg) or phlegmasia cerulea dolens (blue swollen leg). Venous gangrene may occur if the phlegmasia is not aggressively treated. This occurs when the arterial inflow becomes obstructed due to the effects of the venous hypertension. Alternatively, arterial emboli or spasm may occur and contribute to the pathology. Skin blisters and toes on the limb may turn black. Venous gangrene is often associated with an underlying malignancy and is always preceded by phlegmasia cerulea dolens. Amputation rates of 20% to 50%, PE rates of 12% to 40%, and mortality rates of 20% to 40% are associated with venous gangrene.⁶

Tests of historical interest for making the diagnosis of DVT include indirect flow examinations. Presently, duplex ultrasound imaging has replaced these indirect tests due to its high sensitivity, specificity, and reproducibility. Duplex has also replaced the invasive test contrast phlebography. Duplex ultrasound imaging includes both a B-mode image and Doppler flow pattern. Duplex imaging demonstrates sensitivity and specificity rates greater than 95%.⁷ According to the grade criteria for the strength of medical evidence, duplex ultrasound is given a 2 C level of evidence.⁷⁻⁹ Other tests include magnetic resonance imaging (especially good for assessing central pelvic vein and inferior vena cava [IVC] thrombosis), and spiral CT scanning (especially with chest imaging during examination for PE).¹⁰ Even at the level of the calf, a level in which duplex imaging is less accurate, it has become an acceptable technique in symptomatic patients. Duplex imaging is painless, requires no

contrast, can be repeated, and is safe during pregnancy. It is important that it also identifies other causes of a patient's symptoms other than DVT.⁸

A single complete technically adequate negative duplex scan is accurate enough to justify withholding anticoagulation with liminal long-term adverse thromboembolic complications.¹¹ This requires that all venous segments of the leg have been imaged and evaluated. If the duplex scan is indeterminate, treatment may be based on other factors, such as biomarkers, with the duplex scan repeated in 24 to 72 hours. Combining clinical characteristics with a D-dimer assay may decrease the number of negative duplex scans performed.⁵ Also, repeat imaging should be performed if the patient's symptoms change or worsen. Although clinical characteristics and D-dimer levels are useful to rule out thrombosis, the converse is not true. A positive D-dimer and a positive risk assessment is associated with DVT in only approximately 70% of cases.¹² Ongoing efforts to establish a panel of biomarkers that may be used to make a positive diagnosis of DVT based on the inflammatory response to DVT are under investigation.¹³

Other conditions that may be confused with DVT include lymphedema, muscle strains, and muscle contusion. Iliac vein obstruction may lead to unilateral leg edema (May-Thurner Syndrome), whereas the presence of a cyst behind the knee may produce unilateral lower leg pain and edema. Other causes of leg swelling include systemic problems such as cardiac, renal, or hepatic abnormalities. However, these systemic problems usually lead to bilateral edema.

Pulmonary Embolism. In the past, the diagnosis of PE was made with ventilation-perfusion (V/Q) scanning and pulmonary angiography. However, newer techniques include spiral computed tomographic scanning and magnetic resonance imaging. The sensitivity of V/Q scanning was defined in PIOPED I at 98%, but specificity was low at 10%.¹⁴ By combining clinical factors with V/Q scan, levels of sensitivity and specificity greater than 95% were achieved. With a high-probability V/Q scan, two risk factors positive for PE, the sensitivity was 97%; with one risk factor, 84%; and with no risk factors, 82%. Similarly, with a normal V/Q scan, the chance of PE was essentially 0, irrespective of the risk factor status.¹⁵ Thus, a normal V/Q scan or a high-probability scan provided good diagnostic information on which treatment could be based. However, only a small

portion of V/Q scans are in one of these two categories, leaving many patients needing further testing. Due to its invasive nature, pulmonary angiography is used less often today. Pulmonary arteriography is indicated with acute massive PE, IVC interruption, and when planning interventional therapy, such as thrombolysis or pulmonary embolectomy.

Spiral computed tomographic scanning has demonstrated excellent specificity and sensitivity as the technology has improved. Now emboli at the subsegmental level can be identified.¹⁶ The sensitivity for isolated chest CT imaging is increased greater than 90% when clinical analysis is added. Additionally, sensitivity improved when a lower extremity imaging study was added to the chest scan.¹⁰ Results from PIOPED II demonstrate that if the clinical presentation and spiral CT scan results are concordant, therapies can be safely recommended. However, if results are discordant between clinical presentation and spiral CT, then other confirmatory tests are necessary. For the diagnosis of PE, spiral CT imaging is given a 1 A level of evidence. Magnetic resonance imaging is currently being investigated in PIOPED III.

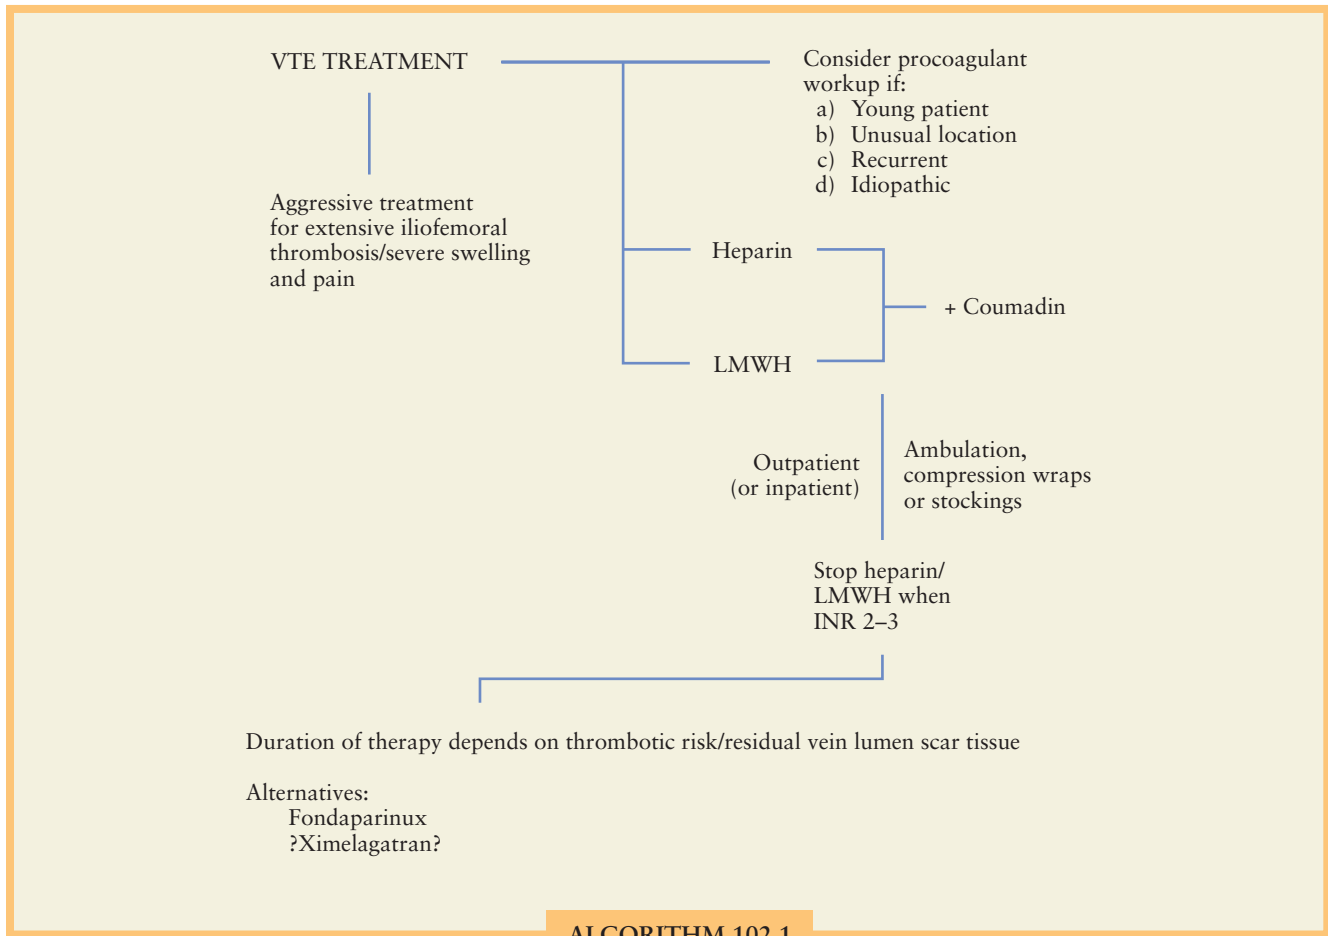

Axillary/Subclavian Vein Thrombosis. Thrombosis of the axillary/subclavian vein accounts for less than 5% of all cases of acute DVT. However, it may be associated with PE in up to 10% to 15% of cases and additionally can also be the source of significant disability.¹⁷ Primary axillary/subclavian vein thrombosis results from obstruction of the axillary vein in the thoracic outlet, the so-called Paget-von Schrötter syndrome, noted especially in healthy muscular athletic individuals. Such thrombosis may also occur in patients with hypercoagulable states. Secondary axillary/subclavian vein thrombosis results include mediastinal tumors, congestive heart failure, and nephrotic syndrome. Patients with axillary-subclavian venous thrombosis often present with arm pain, edema, and cyanosis. Superficial venous distention may be apparent over the arm, forearm, shoulder, and even the anterior chest wall.

Upper extremity venous duplex ultrasound is used to make the diagnosis of suspected axillary-subclavian vein thrombosis. Thrombolysis and phlebography are often considered next. If phlebography is performed, it is important that the patient undergo positional phlebography with arm abduction to 120 degrees to confirm extrinsic subclavian vein compression at the thoracic outlet. Venous compromise is further evidenced by prominent collateral veins. Since a cervical rib may be the cause of such obstruction, chest x-ray views should be obtained to exclude its presence.

STANDARD THERAPY FOR VTE

The primary treatment of VTE is systemic anticoagulation (Algorithm 102.1). This reduces the risk of PE, extension of thrombosis, and thrombus recurrence. Since it has been shown that the recurrence rate for VTE is higher if anticoagulation is not therapeutic in the first 24 hours, immediate anticoagulation should be undertaken.¹⁸ However, recurrent DVT may still occur in up to one third of patients over an 8-year period, even with appropriate anticoagulant therapy.¹⁹

Unfractionated heparin or low-molecular-weight heparin (LMWH) is undertaken for 5 days during which time oral anticoagulation with vitamin K antagonists (usually warfarin) is started. It is recommended that international normalized ratios (INRs) be therapeutic for two consecutive days before stopping heparin or LMWH.²⁰ LMWHs, derived from the lower-molecular-weight range of standard heparin, have become the standard for treatment. They can be given by subcutaneous route, require no monitoring except in certain circumstances (morbid obesity, pregnancy, or renal insufficiency), and are associated with a lower bleeding potential.²¹ Additionally, they

ALGORITHM 102.1

ALGORITHM 102.1. Treatment of venous thromboembolism.

demonstrate less direct thrombin inhibition and more factor Xa inhibition. Compared to standard unfractionated heparin, LMWHs have significant improvement in bioavailability, less endothelial cell binding and protein binding as compared to standard unfractionated heparin, and due to this an improved pharmacokinetic profile.²² Additionally, other potential advantages of LMWHs compared to standard unfractionated heparin include less bleeding, less antiplatelet activity, less frequent heparin-induced thrombocytopenia, less interference with protein C and complement activation, and less osteoporosis. LMWHs are administered in a weight-based fashion subcutaneously. However, the use in outpatient settings usually requires a coordinated effort of multiple healthcare providers. LMWH may also decrease the incidence of postthrombotic syndrome.²³ Based on all of the available evidence, LMWH is now preferred over standard unfractionated heparin for the initial treatment of VTE with a 1 A level of evidence.²⁴

Warfarin should be started after heparinization is therapeutic to prevent warfarin-induced skin necrosis. For standard unfractionated heparin, this would mean after a therapeutic aPTT was obtained, whereas for LMWH, this would mean after an appropriate weight-based dose was administered and had been allowed to circulate. Warfarin causes inhibition of protein C and S before factors II, IX, and X. Thus, patients can be transiently hypercoagulable on the initiation of warfarin therapy. The goal for warfarin dosing is an INR between 2.0 and 3.0. The duration of anticoagulation depends on several factors, including the presence of continuing thrombotic risk factors, the type of thrombosis (idiopathic, for example), the number of times thrombosis has occurred, the status of the

veins when stopping anticoagulation, and the level of D-dimer noted 1 month after warfarin therapy stops. The recommended duration of anticoagulation after a first episode of VTE is 3 to 6 months.²⁵ Calf thrombi may be treated with a shorter course of warfarin, usually 6 weeks to 3 months. After a second episode of VTE, the usual recommendation is prolonged warfarin unless the patient is very young at the time of presentation or there are other mitigating factors. In aggregate, criteria for discontinuation of warfarin are given a 1 A level of evidence.²⁶

VTE recurrence is increased with homozygous factor V Leiden and prothrombin 20210 A mutation, protein C/S deficiency, antithrombin deficiency, antiphospholipid antibodies, and cancer until resolved. In these conditions, long-term warfarin is usually recommended. However, heterozygous factor V Leiden and prothrombin 20210 A genetic abnormalities do not carry the same risk as their homozygous counterparts, and the length of oral anticoagulation is shortened correspondingly.

Although the amount of scar tissue inside the venous circulation leading to stasis has recently been suggested to be an important factor, a better validated factor involves D-dimer testing obtained one month after warfarin is complete. If D-dimer is elevated above normal, warfarin should be continued, as this result suggests that the patient is still prothrombotic.²⁷⁻²⁹ One study demonstrated a statistically significant advantage to resuming Coumadin if the D-dimer assay is elevated over an average 1.4 year follow-up (odds ratio [OR] 4.26, $p = 0.02$).³⁰

Regarding idiopathic DVT, most believe this diagnosis requires more than 6 months of anticoagulation, but the actual

length is unknown. One multicenter trial suggested low-dose warfarin (INR 1.5–2.0) is superior to placebo with a 64% risk reduction for recurrent DVT after the completion of an initial 6 months of standard therapy.³¹ A second study has suggested that full-dose warfarin (INR 2–3) is superior to low-dose warfarin in these patients without a difference in bleeding.³² Taken together, criteria for discontinuation of anticoagulation including thrombosis risk, residual thrombus burden, and coagulation system activation are given a 1 A level of evidence.^{26–29,31,32}

Bleeding is the most common complication of anticoagulation. With standard heparin, bleeding occurs over the first 5 days in approximately 10% of cases. With the addition of warfarin at an INR of 2–3, the incidence of major bleeding approximates 6% per year. When treating patients for DVT and PE, major bleeding has been reported in 0 to 7% of patients, and fatal bleeding has been reported in 0 to 2% of patients.³³ A meta-analysis showed a rate of hemorrhagic complications at 9.1% for anticoagulation continued beyond 3 months. To decrease bleeding, the importance of clinics that monitor oral anticoagulation must be emphasized.

Another complication of heparin is heparin-induced thrombocytopenia (HIT). This heparin complication occurs in 0.6% to 30% of patients. While historically morbidity and mortality have been high, it has been found that early diagnosis and appropriate treatment have decreased these rates.³⁴ The condition of HIT usually begins between 3 and 14 days after heparin is begun, although it may occur earlier if the patient has been exposed to heparin in the past. The pathophysiology involves a heparin-dependent antibody that binds to platelets, activates them leading to an increase in thrombocytopenia, and may result in both arterial and venous thrombosis.³⁵ Both bovine and porcine unfractionated heparin (UFH), as well as LMWH, have been associated with HIT, although the incidence with LMWH is less, and with LMWH, the severity of the thrombosis is also less. Even small exposures to heparin, such as heparin coating on indwelling catheters, has caused the syndrome. The diagnosis should be suspected with a 50% or greater drop in platelet count, when the platelet count falls below 100,000/ μ L during heparin therapy, or when thrombosis occurs during heparin or LMWH therapy.³⁶ Although there are many tests for this diagnosis, the most useful is an enzyme-linked immunosorbent assay (ELISA) that detects the antiheparin antibody in plasma. This test is highly sensitive but poorly specific. The serotonin release assay is another test that can be used. This test is more specific but less sensitive than the ELISA test.³⁷ When the diagnosis is made, cessation of heparin is most important. Warfarin should not be given until an adequate alternative anticoagulant has been established to prevent paradoxical thrombosis as warfarin-induced thrombosis has been reported with this condition. As LMWHs demonstrate high cross-reactivity with standard heparin antibodies, they cannot be substituted for standard heparin in patients with HIT. Agents that have been FDA approved as alternatives for HIT include the direct thrombin inhibitors hirudin (lepirudin/Refludan) and argatroban. Other agents have also been found to be effective, such as fondaparinux, but they are not FDA approved for this indication.^{38,39} The use of these alternative agents is given either a 2 C or 1 C level of evidence.^{26,36,38,39}

Low-Molecular-Weight Heparin Special Features

When considering once a day to twice a day LMWH dosing, a meta-analysis of more than 1,500 patients with VTE demonstrated a nonsignificant difference in the incidence of recurrent thromboembolism, thrombosis size, hemorrhagic events, and mortality.⁴⁰ Twice a day dosing may still be more appropriate

than once a day dosing in patients with marked obesity and patients with cancer.⁴¹

LMWH has been suggested as a replacement for oral vitamin K antagonists. Rates of recanalization have been reported to be higher in certain venous segments using LMWH, and the use of LMWH has been found to lead to improved outcomes in cancer patients compared to standard heparin or LMWH/warfarin therapy when used for 6 months, without differences in rates of major bleeding.⁴² LMWH has also been found to provide better DVT prophylaxis than placebo when used for extended prophylaxis over 4 weeks in patients undergoing abdominal and pelvic cancer surgery.⁴³

ALTERNATIVE/FUTURE MEDICAL TREATMENTS FOR DVT/PE

New agents for venous thrombosis treatment include direct thrombin inhibitors and factor Xa inhibitors (Table 102.2). Ximelagatran, a direct thrombin inhibitor, caused an elevation in liver function tests in up to 6% of patients given the drug and was not approved in either the United States or in Europe. A relative of this drug, dabigatran etexilate, is currently undergoing phase III studies in the treatment of VTE and has met a noninflammatory target compared to Enoxaparin in prophylaxis for orthopedic procedures. It is important that no elevation in liver enzymes or acute coronary events has been found.⁴⁴

Fondaparinux and its relative idraparinux target factor Xa. These subcutaneous drugs show a 17-hour half-life for fondaparinux and 80 to 130 hours for idraparinux. They exhibit no endothelial or protein binding, and neither produces thrombocytopenia. One disadvantage of these drugs is that no antidote is readily available. Fondaparinux has been tested in the prophylaxis of major orthopedic surgery. In a meta-analysis

TABLE 102.2

ALTERNATIVE ANTICOAGULANTS

■ DRUGS	■ MECHANISM OF ACTION
Dabigatran etexilate	Direct thrombin (FIIa) inhibitor
Lepirudin	Direct thrombin (FIIa) inhibitor
Bivalirudin	Direct thrombin (FIIa) inhibitor
Argatroban	Direct thrombin (FIIa) inhibitor
Fondaparinux	Indirect FXa inhibitor
Idraparinux	Indirect FXa inhibitor
Rivaroxaban	Direct FXa inhibitor
Apixaban	Direct FXa inhibitor
Oral heparins/LMWH	Same as heparin/LMWH with passage through GI tract
Ancrod	Defibrinating agent
P-selectin inhibitors	Anti-inflammatory preventing thrombus amplification
Factor VIIa inhibitors	Competes with FVIIa for binding to TF
Tissue factor pathway inhibitor	FVIIa/TF complex inhibitor
Activated protein C	Inactivates FVa, FVIIIa, inhibitor to tPA

FIIa, factor IIa; FXa, factor Xa; FVIIa, factor VIIa; FVIIIa, factor VIIIa; FVa, factor Va; TF, tissue factor; tPA, tissue plasminogen activator.

involving more than 7,000 patients, there was a greater than 50% risk reduction for VTE using fondaparinux begun 6 hours after surgery compared to LMWH begun 12 to 24 hours after surgery.⁴⁵ Critical bleeding was not different, although major bleeding was increased. Fondaparinux has also been effective in prophylaxis of general medical patients, abdominal surgery patients, and for extended prophylaxis after hip fracture.^{46–48} For DVT treatment, fondaparinux was found equal to LMWH whereas for PE, it was found equal to standard heparin.^{49,50} Dosage is based on body weight—5 mg per body weight less than 50 kg; 7.5 mg per body weight 50 to 100 kg; and 10 mg per body weight greater than 100 kg. Treatment for at least 5 days with concurrent administration of oral anticoagulation is recommended, until the INR is therapeutic at a level of 2 to 3. Fondaparinux has been approved for the treatment of DVT/PE and for thrombosis prophylaxis in total hip, total knee, and hip fracture patients; in the extended prophylaxis of hip fracture patients; and in abdominal surgery patients. Idaraparinux with the longer half-life in an open label, noninferiority trial of 2,904 DVT patients and 2,215 PE patients was found to meet the noninferiority requirement of DVT, but not of PE.⁵¹ This may have been due to a dose problem. Additionally, in a study of long-term treatment, major bleeding was found with three intracranial bleeding episodes noted.⁵¹ Thus, idraparinix development has been halted. However, biotinylated idraparinix is being tested; this drug, called SSR 126517, can be reversed with avidin. Phase III trials are currently underway with this drug.⁵²
